30 **Abstract**

31 We extend the *Bayesloc* seismic multiple-event location algorithm for application to global  
32 arrival time data sets. *Bayesloc* is a formulation of the joint probability distribution across  
33 multiple-event location parameters, including hypocenters, travel time corrections, pick  
34 precision, and phase labels. Stochastic priors may be used to constrain any of the *Bayesloc*  
35 parameters. Markov Chain Monte Carlo (MCMC) sampling is used to draw samples from the  
36 joint probability distribution, and the posteriori samples are summarized to infer conventional  
37 location parameters such as the hypocenter. The first application of the broad-area *Bayesloc*  
38 algorithm is to a data set consisting of all well-recorded events in the Middle East and the most  
39 well-recorded events with  $5^\circ$  spatial sampling globally. This sampling strategy is designed to  
40 provide the ray coverage needed to determine lithospheric-scale P-wave velocity structure in the  
41 Middle East using the complementary ray geometry provided by regional (sub-horizontal) and  
42 teleseismic (sub-vertical) ray paths, and to determine a consistent – albeit lower resolution –  
43 image of global mantle structure. The data set consists of 5401 events and 878,535  $P$ ,  $P_n$ ,  $pP$ ,  $sP$ ,  
44 and  $PcP$  arrivals recorded at 4606 stations. Relocated epicenters are an average of 16 km from  
45 bulletin locations. Epicenters are found to be within 5.6 km on average from epicenters that are  
46 known to within 1 km (e.g. nuclear explosions). For arrivals labeled  $P$ ,  $P_n$ , and  $PcP$ ,  $\sim 92\%$ ,  
47  $\sim 90\%$ , and  $96\%$  are properly labeled with probability  $> 0.9$ , respectively. Incorrect phase labels  
48 are found to be erroneous at rates of 0.6%, 0.2%, 1.6%, and 2.5% for  $P$ ,  $P_n$ ,  $PcP$ , and depth  
49 phases ( $pP$  and  $sP$ ), respectively. Labels found to be incorrect, but not erroneous, were  
50 reassigned to another phase label.  $P$  and  $P_n$  residual standard deviation with respect to *ak135*  
51 travel times are dramatically reduced from 3.45 seconds to 1.01 seconds. The differences  
52 between travel time residuals for nearly reciprocal ray paths are significantly reduced from the

53 input event locations, suggesting that *Bayesloc* relocation improves data set consistency. This  
54 results also suggest that the dominant contribution to travel time residuals calculated from  
55 information provided in global bulletins is location and picks errors, not travel time prediction  
56 errors due to 3-D structure. Modeling the whole multiple-event system results in accurate  
57 locations and an internally consistent data set that is ideal for tomography and other travel time  
58 calibration studies. *Simmons et al.* (companion paper) use the *Bayesloc*-processed data set to  
59 develop a 3-D tomographic image, which further reduces residual standard deviation to 0.50  
60 seconds.  
61

62 **1. Introduction**

63 Production of accurate global and regional seismic bulletins for use in Earth model  
64 development and empirical travel time calibration remains a painstaking and costly endeavor.  
65 The International Seismic Centre (ISC) produces the most comprehensive bulletin of seismic  
66 event information, containing reconciled arrival time measurements (picks) and event  
67 hypocenters based on data contributions from the National Earthquake Information Center  
68 (NEIC) and numerous regional- and local-network operators. As such, the ISC bulletin is the  
69 summary of an impressive international effort to analyze a massive stream of global seismic  
70 data. Despite the wealth of information contained within the ISC bulletin, direct use of the ISC  
71 bulletin (or constituent bulletins) in travel time tomography has been discounted. A number of  
72 investigations find that tomographic signal – the component of a travel time residual attributed to  
73 deviation from a reference Earth model – is obscured by errant picks and substantial hypocenter  
74 errors [e.g. *Grand 1990; Gundmundsson et al. 1990; Creager and Boyed 1992; Roehm et al.*  
75 *1999; Husen et al. 2009*].

76 Recognizing both the wealth of information in the ISC bulletin, as well as data quality  
77 issues, *Engdahl et al. [1998]* developed and applied methods to identify and remove pick outliers  
78 and to correct phase-naming mistakes. *Engdahl et al. [1998]* also made use of core phases (e.g.  
79 *PKP*) and secondary phases (*pP, sP, pwP*) to relocate and improve hypocenter accuracy. The  
80 resulting bulletin (EHB hereafter) remains the most utilized data set for the development of  
81 global P-wave tomography models [e.g. *van der Hilst et al. 1997; Kennett et al. 1998; Bijwaard*  
82 *et al. 1998; Boschi and Dziewonski 1999; Káráson and van der Hilst 2000; Antolik et al. 2003;*  
83 *Montelli et al. 2004*]. *Li et al. [2008]* make use of teleseismic and regional EHB data to develop,  
84 arguably, the most comprehensive image of mantle P-wave structure to date. The EHB bulletin

85 continues to evolve as detailed analysis of individual events and multiple-event analysis of event  
86 clusters (e.g. aftershock sequences) are completed [e.g. *Bondár et al.* 2008, 2009]. However,  
87 inaccuracies and inconsistencies are inevitable for bulletins that are based on single-event  
88 locations; because additions and improvements are generally made one event at a time.

89 Other approaches use waveform cross correlation to make exceedingly precise arrival-  
90 time measurements. Recorded signals can be cross correlated with synthetic seismograms [e.g.  
91 *Grand* 1994, 2002; *Simmons et al.* 2006, 2007], or many waveforms for a single event can be  
92 cross correlated to obtain relative arrival times [e.g *Masters et al.* 2000; *Bolton and Masters*  
93 2001; *Ritsema and van Heijst* 2002; *Houser et al.* 2008]. Despite producing exceedingly precise  
94 measurements, application of correlation methods is currently limited to long-period, teleseismic  
95 signals. Unlike teleseismic waveforms, widespread waveform similarity for recorded regional  
96 waveforms is uncommon, which severely limits the applicability of empirical waveform  
97 correlation. Matching synthetic and empirical regional waveforms is similarly challenging;  
98 because, region-specific models – or fully 3-dimensional models – are needed in order to  
99 adequately match observed regional waveforms. As a result, waveform methods require further  
100 development before a self-consistent regional and teleseismic data can be produced.

101 In this study we continue the effort to improve the accuracy and consistency of bulletin  
102 data, by adapting the *Bayesloc* method [*Myers et al.* 2007, 2009] of multiple-event location for  
103 application to global seismicity. *Bayesloc* is a formulation of the joint probability function that  
104 spans hypocenters, travel-time corrections, pick precision, and phase labels. Previous versions of  
105 *Bayesloc* were tailored for application to event clusters (e.g. aftershock sequences), with travel-  
106 time correction and pick precision formulations that are designed for robustness. Application to  
107 a global data set requires a more general formulation. Specifically, the formulation must enable

108 datum-specific assessment of travel time correction and pick precision, while maintaining  
109 robustness. The updated *Bayesloc* algorithm enables production of an accurate and consistent  
110 global/regional bulletin by simultaneously relocating events, assessing pick precision, a more  
111 generalized travel time correction, and probabilistically assessing phase labels. Assessment of  
112 phase labels includes the possibility that an arrival-time datum is erroneous. *Bayesloc* allows  
113 prior constraints on any aspect of the multiple-event system, enabling directly utilization of  
114 previous work that statistically characterizes the accuracy of event hypocenters and picks [e.g.  
115 *Bondár et al.* 2004; *Bondár and McLaughlin* 2009]. The use of prior information helps to  
116 mitigate regional location bias and improve outlier identification. The first application is to a  
117 data set of all well-recorded events in the Middle East and an even sampling of the best-recorded  
118 events sampling the globe.

119

## 120 **2. Method**

### 121 **2.1 Multi-Event Relocation**

122 Multiple-event methods simultaneously invert arrival times for many events to determine  
123 both event locations and a set of travel-time corrections. Travel-time corrections typically take  
124 the form of station/phase terms [e.g. *Douglas* 1967], which restricts applicability to instances  
125 where travel time prediction errors at a station and for a given phase are approximately equal for  
126 all events (e.g. event clusters). Multiple event methods are known for generating precise relative  
127 locations, but loss of location accuracy is inherent to the unconstrained station/phase  
128 formulation, resulting in consistent location bias [*Douglas* 1967; *Jordan and Sverdrup* 1981;  
129 *Pavlis and Booker* 1983]. *Waldhauser and Ellsworth* [2000] mitigate the limitations of the  
130 station phase term by solving for event locations based on residual differences (a.k.a. double

131 difference) and allowing the residual difference to vary slowly with event location. *Menke and*  
132 *Schaff* [2004] show that double difference methods can resolve absolute location if network  
133 coverage is outstanding.

134 The *Bayesloc* method [*Myers et al.* 2007] parameterizes the travel time correction as an  
135 adjustment to the travel time curve for each phase, with the addition of station terms with a zero-  
136 mean prior. Correcting the travel time curve mitigates gross travel time prediction errors, and  
137 zero-mean station-phase terms maintains resolution of absolute location while accounting for  
138 path-specific travel time variations. This formulation is robust to poor network configuration,  
139 allowing broader application of the multiple-event method.

140 In addition to precise locations, multiple-event relocation can be used to identify and  
141 remove outlier data [e.g. *Engdahl and Bergman* 2001]. In single-event algorithms, the event  
142 location can move significantly to accommodate an outlier datum; because, the tolerance for  
143 overall arrival time misfit is relatively large. In multiple-event locators, the use of a self-  
144 consistent set of travel time correction parameters significantly reduces the tolerance for arrival  
145 time misfit. Reduced tolerance for data misfit reduces the distance that an event location can  
146 move to better fit an outlier datum, which results in a larger residual for outlier data. Further, an  
147 outlier residual is more confidently identified in the context of many events recorded at a  
148 common station.

149

## 150 **2.2 *Bayesloc* modified for a global data set**

151 *Bayesloc* is a statistical model of the multiple event system, including event locations,  
152 travel time corrections, assessments of arrival-time measurement (pick) precision, and phase  
153 labels. The overarching statistical model is

154

$$155 \quad p(o, x, T, W, \sigma, \tau | a, w) = \frac{p(a | o, T, W, \sigma) p(T(x) | F(x), \tau)}{p(x, o) p(\sigma) p(\tau) p(W | w) / p(a)} \quad (1)$$

156

157 where  $o$  represents event origin times,  $x$  represents event locations,  $T$  is the collection of travel  
158 times from each event to each station for each phase (model-based prediction plus correction),  $W$   
159 is the collection of all phase labels,  $\tau$  is a collection of travel time correction parameters,  $\sigma$  is the  
160 collection of arrival-time precision parameters,  $a$  and  $w$  are the collection of arrival times and  
161 input phase labels. Equation 1 decomposes the inversion of arrival time data to solve for the  
162 components of the multiple-event system (left-hand side of equation 1), into a collection of  
163 “forward” problems and prior constraints (right-hand side of equation 1). Specifically, the first  
164 term (right-hand side) computes the probability of observing the collection of arrivals given a set  
165 of hypocenters, travel times, phase labels, and pick precisions. The second term computes the  
166 probability of all travel times, given a model-based prediction (event location is implicit) and a  
167 collection of correction parameters. The third, fourth, fifth, and sixth terms are prior constraints  
168 on hypocenters, arrival-time measurement precision parameters, travel time correction  
169 parameters, and input phase labels, respectively. The denominator is the probability over all  
170 arrival data, which serves as normalization. Analytical expressions for each term in equation 1  
171 are provided in *Myers et al.* [2007, 2009].

172 *Bayesloc* uses the Markov-Chain Monte Carlo (MCMC) method to sample the joint  
173 probability of the multiple-event system [see *Gelman et al.* 2004]. Sampling the probability  
174 function is accomplished by starting with an initial configuration of the system, then randomly  
175 proposing a new configuration using specifically designed proposal distributions (See *Myers et*  
176 *al.*, 2007, 2009). The probability of the current and proposed multiple-event configuration is

177 computed using the forward calculations afforded by Equation 1. A proposed configuration is  
 178 always accepted as the new “state” of the system if the probability is greater than the current  
 179 state. If the probability of the proposed state is lower than the current state, then the new state is  
 180 accepted at a rate specified by the ratio of the probability for the proposed state and the current  
 181 state. Clearly, configurations of event locations and travel time corrections that reduce arrival  
 182 time residuals are higher probability configurations and are, therefore, preferred by the MCMC  
 183 algorithm. Likewise, fitting residuals with representative arrival-time measurement precision  
 184 (1/variance) parameters maximizes probability by including the most data within the high  
 185 probability portion of the distribution.

186         The process of accepting/rejecting proposed configurations is continued until adequate  
 187 sampling of the joint probability density is achieved (typically 10,000 to 20,000 iterations).  
 188 Graphical examination of the MCMC samples can be used to assess the non-parametric  
 189 probability density or an analytical form (e.g. Gaussian) may be used to summarize the MCMC  
 190 samples. For example, the mean or mode of latitude and longitude samples for given event may  
 191 be used as an epicenter estimate, and an epicenter uncertainty ellipse can be computed from the  
 192 latitude and longitude covariance.

193         Myers *et al.* [2007, 2009] implement simple adjustments to the travel time curve and a  
 194 collection of station terms with a prior mean of zero to robustly correct for gross prediction  
 195 errors. The travel time curve adjustment formulation is suitable for event clusters, where a  
 196 station term can adequately capture deviations from the adjusted travel-time curve. However,  
 197 travel time corrections must be path specific in order to apply *Bayesloc* to a broad-area data set.  
 198 As such, we recast the *Bayesloc* travel time correction as,

$$199 \quad \delta_{ijw} = T_{ijw} - F_{ijw} = \alpha_w + \alpha_i + \alpha_j + \alpha_{iw} + \alpha_{jw} + \beta_w \|x_i - s_j\|, \quad (2)$$

200 where  $\delta$  is the travel time correction,  $T$  is the corrected travel time,  $F$  is the model-based travel  
201 time, and  $\beta$  is an adjustment to the slope of the travel time curve. The double bars in the  $\beta$  term  
202 indicate event-station distance and the variables  $x$  and  $s$  represent event and station positions,  
203 respectively. The  $\alpha$  terms are static corrections attributed to a station ( $j$ ), event ( $i$ ), phase ( $W$ ) or  
204 combination thereof. Realizations for each category of  $\alpha$  term ( $\alpha_i, \alpha_j, \alpha_{iw}, \alpha_{jw}$ ) are drawn from a  
205 zero-mean Gaussian distribution with unknown variance. The variance of each  $\alpha$  term is  
206 estimated throughout Bayesloc sampling. In effect, station and event terms ( $\alpha_i, \alpha_j$ ) are small  
207 corrections with respect to the corrected travel time curve ( $F_w + \alpha_w + b_w ||x_i - s_j||$ ) and the station-  
208 phase and event-phase terms ( $\alpha_{iw}, \alpha_{jw}$ ) can further refine the travel time correction.  
209 Decomposition of terms in this way allows robust determination of station and event corrections,  
210 with resolution of event-phase and station-phase corrections if sufficient data are available. In the  
211 absence of sufficient data  $\alpha$  terms will tend towards zero.

212

### 213 **3. Data Set**

#### 214 **3.1. Event selection and data sources**

215 For the first application of *Bayesloc* to a broad-area data set we have gathered a list of  
216 5,401 events throughout the Middle East and well-recorded events that provide global epicenter  
217 coverage. Arrival time data and event locations are drawn from the EHB bulletin [*Engdahl et al.*  
218 1998] and a subset of the Lawrence Livermore National Laboratory (LLNL) database [see  
219 *Ruppert et al.* 2005]. The LLNL database contains a compilation of global and regional bulletins  
220 as well as ~20,000 travel time measurements at regional stations ( $P_n$ ) made by LLNL staff. The  
221 data set contains over 4,000 events in the Middle East region. Outside of the Middle East, the  
222 best-recorded events with epicenter spacing of  $\sim 5^\circ$  achieve broad global sampling. Sampling of

223 the global data set is accomplished by selecting the event with the most teleseismic P-phase  
224 arrivals and removing all other events within  $\sim 5^\circ$  arc distance of the selected event. The process  
225 is repeated until the event list is exhausted. In order to preserve the depth sampling afforded by  
226 the EHB bulletin, geographic event sampling is conducted in depth bins with lower bounds of 35  
227 km, 75 km, 150km, 300 km, 450 km, and 700 km. All together, 878,535 *P*, *P<sub>n</sub>*, *pP*, *sP*, and *PcP*  
228 arrivals recorded at 4,606 stations comprise the data set (Figure 1). Table 1 lists the number of  
229 arrivals for each phase.

230 The event sampling strategy is designed to provide the ray coverage needed to determine  
231 lithospheric-scale structure in the Middle East using the complementary ray geometry provided  
232 by regional (sub-horizontal) and teleseismic (sub-vertical) ray paths, and to determine a  
233 consistent – albeit lower resolution – image of global mantle structure. *Simmons et al.* (this  
234 volume) report on the tomography study using the *Bayesloc* bulletin developed in this study.

235

### 236 **3.2 *Bayesloc* Relocation**

237 The *Bayesloc* joint posteriori distribution for the Middle East/Global data set is  
238 determined using 4 Markov Chains. The results presented here are averages of the last 12,000 of  
239 15,000 MCMC samples for each chain. The first 3,000 samples (“burn in”) were used to find the  
240 neighborhood of the mode of the posteriori distribution and to adapt MCMC sampling. As such,  
241 the first 3,000 samples are not necessarily representative of the joint probability density. Chain  
242 mixing – using the parameter configuration of another chain as a proposed configuration – was  
243 used to test for local minima. In order to better sample event locations, the starting position for  
244 each chain was randomly perturbed from the location of the station having the earliest arrival  
245 time pick for that event. Starting depths were set to 15 km, except for depths greater than 70 km

246 as listed in the EHB bulletin, in which case the EHB depth was used as the starting depth. In  
247 addition to using the EHB depths as the starting positions, we place a prior constraint on event  
248 depth of  $\pm 5$  km (standard deviation) for EHB locations with depths greater than 70 km. Our  
249 justification is that EHB depth-phase data were scrutinized for consistency and the effect of slow  
250 wave propagation through the water column was accounted for when the surface bounce point  
251 was determined to be in the ocean.

252 The *ak135* model [Kennett *et al.* 1995] was used for all base-model travel time  
253 predictions. The *Bayesloc* travel time correction model includes a shift and change of slope of  
254 each model-based travel time curve. Myers *et al.* [2007] demonstrate that *Bayesloc* robustly  
255 determines the slope of the travel time curve, so we use non-informative priors on the slope  
256 correction ( $\beta$  in Equation 2). However, resolution of the shift of the travel time curve ( $\alpha_w$  in  
257 Equation 2) requires prior constraints on either the shift itself or prior constraints on some event  
258 origin times. Because the *ak135* model was developed and validated using the limited set of  
259 nuclear explosions with known origin times and using locally recorded events, for which the  
260 origin time is well constrained [Kennett *et al.* 1995], the absolute travel time for teleseismic  
261 phases cannot be improved in this study. Therefore, we place tight constraints on the shift of  
262 teleseismic travel time curves ( $P$ ,  $pP$ ,  $sP$ ,  $PcP$ ). Unlike teleseismic phases, *ak135* travel time  
263 errors for the regional  $P_n$  phase are exceedingly non-stationary, with regional biases of many  
264 seconds. We allow *Bayesloc* to model the regional  $P_n$  travel time bias in the Middle East by  
265 placing a loose prior on the shift of the travel time curve of  $\pm 5$  seconds (standard deviation).

266 In addition to travel time curve corrections, the *Bayesloc* travel time correction model  
267 includes event, station, event-phase, and station-phase parameters. Prior constraints on the  
268 standard deviation of these parameters are uninformative, but a prior mean value of zero for the

269 collection of each parameter category is imposed. Prior constraints on the measurement precision  
270 are also uninformative, so data weighting is entirely determined by adapting precision  
271 parameters to fit data distributions during the MCMC sampling. Last, MCMC phase label  
272 sampling is set so that if an alternative phase labels is tested, than there is an equal chance that  
273 the label will be one of the other phases under consideration or the “erroneous” label.

274

## 275 **4. Results**

### 276 **4.1. Epicenter shifts**

277 Figure 2 shows epicenter shifts for all of the global events and a representative sampling  
278 of events in the Middle East. Epicenters shift by 16 km on average relative to the input bulletin  
279 locations, and regional trends in the vector directions are evident. Eight of the events in the  
280 global data set are listed in the IASPEI Reference Event List [*Bondár and McLaughlin 2009*]  
281 with location accuracy of 1 km or better. The average difference between reference epicenters  
282 and *Bayesloc* epicenters is 5.6 km. This result suggests that the *Bayesloc* locations are  
283 substantially more accurate than the bulletin location given that the average epicenter shift is far  
284 larger than the error with respect to known locations.

285 The shift in position from the starting (single-event) epicenter to the *Bayesloc* epicenter is  
286 not random (Figure 2). The consistency and magnitude of epicenter shifts for events in and near  
287 subduction zones are particularly strong. The direction of epicenter shifts in subduction zones  
288 tends to be toward the subduction trench, which is consistent with the expected shift due to a slab  
289 of fast oceanic lithosphere dipping under the overriding plate [*Creager and Boyed 1992*].  
290 Outside of subduction zones, epicenters tend to shift northward in the Pacific basin, eastward in  
291 Africa, and southward in the Middle East. Little shift is observed throughout northern Asia,

292 because most of the events are nuclear explosions for which the known location is listed in the  
293 EHB bulletin.

294

### 295 *Location Example*

296 Figure 3 shows the location of the May 28, 1998 Pakistan nuclear explosion and *Bayesloc*  
297 location predictions. The event was well recorded, but station sampling is not geographically  
298 uniform. Residual travel times at European stations are early (negative residual) with respect to  
299 the known location [Albright *et al.* 1998] and the *ak135* [Kennett *et al.* 1995] travel times. The  
300 predominance of European stations with negative residuals results in a northward epicenter bias  
301 when the *ak135* model is used for travel time prediction (mislocation of 10.1 km). Because the  
302 prediction errors are not random, the resulting epicenter error ellipse does not cover the true  
303 location. *Bayesloc* travel time corrections mitigate travel time prediction bias, resulting in an  
304 epicenter error of 4.5 km. Modeling all components of the location system, including pick and  
305 model error, results in a reduction of the epicenter error ellipse area from 207 km<sup>2</sup> to 70 km<sup>2</sup>.  
306 More importantly, the *Bayesloc* error ellipse covers the known location because the marginal  
307 probability of the event location integrates over the joint probability of all other multiple-event  
308 parameters.

309

## 310 **4.2. *Bayesloc* Posteriori Travel times**

### 311 *Travel Time Curves*

312 The posteriori shift of the  $P_n$  travel time curve is 0.42 seconds, and the slope of the  $P_n$   
313 travel time curve changes significantly. The posteriori slope of the  $P_n$  travel time curve equates  
314 to a phase velocity of 8.16 km/s compared to the starting value of 8.05 km/s for *ak135*. The

315 delay in  $P_n$  travel time is consistent with the thick crust of the Iranian Plateau and the decrease in  
316 slope of the  $P_n$  curve suggests faster upper mantle velocity than the global average. Despite loose  
317 priors on the slope of the  $P$ ,  $PcP$ ,  $pP$ , and  $sP$  travel time curves, the posteriori curves were not  
318 significantly altered in the *Bayesloc* inversion.

319

#### 320 *Data Precision*

321 Application of *Bayesloc* to global data sets with more events and arrivals further  
322 improves the robustness of data precision modeling. The precision for each datum is the product  
323 of an event, a station, and a phase term. Posteriori precision is dominated by pick (measurement)  
324 error, but also includes other errors that may not be accounted for in the travel time correction.  
325 Priors on the pick error were non-informative, resulting in a purely data-driven assessment of  
326 precision. Figure 4 summarizes posteriori precision for the 3 components of the *Bayesloc* error  
327 model. Low precision indicates that no configuration of the multiple-event system could be  
328 found to fit the subset of data for the tested station, phase, or event.

329 The largest variability in precision is found for stations: arrival time data are very  
330 consistent at some stations and inconsistent at others. The variability in precision equates to  
331 station standard deviation ranging from 0.36 seconds to 23.62 seconds. The large variation in  
332 station precision is likely a combination of inconsistent arrival time measurement practices,  
333 station timing errors, and/or errors in the station location. Likewise, arrival times are more  
334 consistently fit for some events than for others, with the variability in event standard deviation  
335 ranging from 0.59 seconds to 6.26 seconds. A possible reason for variations in data fit between  
336 events is that some events (e.g. explosions) generate more impulsive signals, as noted by *Bondár*  
337 *et al.* [2004].

338 Figure 5 is a Gaussian representation of the posteriori data precision for each phase.  
339 Precision is determined relative to the corrected travel times, but we do include the 0.42 s shift in  
340 the  $P_n$  travel time prediction to show the significance of the shift with respect to the overall  $P_n$   
341 distribution.  $P$  is found to be most precisely picked, followed by  $P_n$ ,  $pP$ ,  $PcP$ , and  $sP$ . This  
342 result is consistent with common knowledge that first arrivals ( $P$  and  $P_n$ ), which do not arrive in  
343 the code of earlier phases, are most precisely picked, and the later phases, which generally arrive  
344 soon after the  $P$ -phase, are less precisely picked. A summary of the posteriori pick uncertainty is  
345 listed in Table 1.

346

#### 347 *Phase Labels*

348 MCMC sampling includes testing alternate phase labels for each arrival datum. The  
349 phase labels that increase overall probability are more likely to be accepted, and posteriori  
350 probability is measured by the frequency of each label in the MCMC sample. Posteriori  
351 summary statistics for each phase are listed in Table 1. The 4<sup>th</sup> column of Table 1 lists the  
352 percentage of instances where the input and posteriori phase label agree and the posteriori  
353 probability of the phase label is greater than 0.9. The results suggest that input phase labels are  
354 correct, with high confidence, in approximately 90% of the instances for this data set. The 5<sup>th</sup>  
355 column lists the percentage of instances where the input and most likely posteriori phase label  
356 agree. The 6<sup>th</sup> column lists that percentage of instances where the posteriori phase label was  
357 deemed “erroneous” (i.e. the provided arrival time did not match the timing for any of the phases  
358 considered in this study).

359 The results also suggest that the first-arrival,  $P$  and  $P_n$  phases, are not likely to be  
360 erroneous, but the rate of erroneous data entries for later-arriving phase –  $pP$ ,  $sP$ , and  $PcP$  – is

361 approximately 1% to 2%. The difference between columns 5 and 6 is the rate of phase  
362 misidentification, i.e. valid arrivals with the wrong phase assignment. For example,  
363 approximately 3% of reported  $P$  phases are mislabeled. Detailed examination of the *Bayesloc*  
364 output finds that if a  $P$ -phase is relabeled it is most likely to be relabeled as a depth phase. This  
365 can occur when the  $P$ -phase is on a node of the focal sphere and a depth phase is not nodal. The  
366 depth phase  $pP$  is also commonly relabeled as either another depth phase or as  $P$ . Figure 6  
367 shows an example of phase relabeling with waveforms added to substantiate the *Bayesloc* result.  
368 Clearly the removal of one  $P$ -phase is correct, and relabeling the  $pP$  arrival to  $sP$  is sensible  
369 given the apparent arrival of the true  $pP$  phase that precedes the relabeled phase.

370

### 371 *Travel Time Residuals*

372 *Bayesloc* reduces  $P$  and  $P_n$  residual standard deviation by more than a factor of 3, from  
373 approximately 3.45 s to 1.01 s. The *Bayesloc* data set excludes ~4% of input data that are not  
374 labeled as  $P$  or  $P_n$  with posteriori probability exceeding 0.9, but only a small portion of the  
375 observed reduction in standard deviation can be attributed directly to data removal. Simply  
376 removing 4% of the data comprising the tails of a Gaussian distribution would reduce the  
377 standard deviation from 3.45 to approximately 3.00 seconds. In fact, the observed reduction in  
378 residual standard deviation would require removing approximately 60% of the data comprising  
379 the tails a Gaussian distribution. Reduction of residual standard deviation by a factor 3 through  
380 *Bayesloc* relocation suggests that the dominant contribution to global bulletin residuals is  
381 location and picks errors, rather than the effects of 3-D velocity heterogeneity. This finding is  
382 consistent with the findings of studies referenced in the introduction.

383 Plotting *ak135* travel time residual density as a function of event-station distance (Figure  
384 7) clarifies residual trends. At teleseismic distances, the residual distribution shows a slight  
385 negative trend. Patterns within the body of the residual distribution at between 20° and 50° also  
386 emerge in the *Bayesloc* residuals.  $P_n$  residuals exhibit a distinct negative trend, consistent with  
387 the *Bayesloc* correction to the  $P_n$  travel time curve for the Middle East. The  $P_n$  distribution after  
388 trend removal is slightly larger than the distribution for teleseismic  $P$ , because of increased pick  
389 error and significant velocity heterogeneity in the Middle East region. *Simmons et al.*  
390 (companion paper) use the *Bayesloc* output as input to 3-D tomography. With respect to the 3-D  
391 velocity model, *Bayesloc* residuals become 0 mean with standard deviation of 0.50 seconds.  
392 Moreover, the residual trends as seen in Figure 7 are removed when travel times are predicted on  
393 the basis of the new global tomography model.

394

#### 395 *Data Consistency Measured by Reciprocal-Path Travel Time Residuals*

396 Data set consistency can be measured by differencing travel times for reciprocal paths.  
397 To the extent that reciprocal travel times disagree, residuals cannot be attributed to velocity  
398 model errors and the data set is less desirable for tomography. A truly reciprocal path would  
399 require two events that occur at the location of two seismic stations. For global data sets that are  
400 comprised primarily of earthquakes, reciprocal pairs would be rare indeed, primarily because the  
401 events would have to occur at the surface. We can, however, identify station-event pairs that are  
402 reciprocal within some spatial tolerance. We do not expect the travel times to be identical, but  
403 the residuals with respect to a reference model (*ak135* in this case) should be highly correlated,  
404 because of significant overlap in the ray path sensitivity kernels [*Rodi and Myers 2007*].

405           We identify 150 teleseismic paths with event-station distance between  $15^\circ$  and  $92^\circ$ , and  
406 65 regional paths with event-station distance between  $5^\circ$  and  $15^\circ$ . The maximum distance  
407 (tolerance) between events and stations forming the ends of a reciprocal path is set to  $1^\circ$  for  
408 teleseismic paths and  $0.7^\circ$  for regional paths. This difference between ray end points constitutes  
409 a smaller percentage of the overall path for teleseismic than for regional paths, so we may expect  
410 better agreement for teleseismic reciprocal paths. Decreasing the tolerance for regional reciprocal  
411 paths results in too few paths for meaningful analysis. Only events with depth less than 20 km  
412 are considered.

413           Figure 8 shows reciprocal paths and the differences between residual travel times for  
414 each reciprocal pair. Teleseismic reciprocal paths provide good sampling in the Middle East and  
415 a few paths at the Eastern Pacific Rim. Regional-distance reciprocal paths are entirely in the  
416 Middle East for this data set. The standard deviation of residual differences for input teleseismic  
417 reciprocal paths is 3.1 s, revealing considerable data set inconsistency. The standard deviation of  
418 residual differences for *Bayesloc* teleseismic reciprocal paths is reduced to 0.8 s, suggesting  
419 vastly improved data set consistency. The number of path pairs is dramatically reduced at  
420 regional distances, but the results also show improved data set consistency, with the standard  
421 deviation of residual differences reduced from 1.7 seconds (input) to 1.0 seconds for *Bayesloc*. It  
422 should be noted that although reciprocity tests reveal substantial improvement in data  
423 consistency, the *Bayesloc* procedure did not include reciprocity constraints, and improved  
424 agreement between travel-time residuals for reciprocal paths is primarily an indication of  
425 improved event locations.

426

427 **4. Discussion and Conclusions**

428           Global bulletin arrival times provide the seismic community with a wealth of  
429 information. However, use of bulletin data for the purposes of determining phase travel times is  
430 limited, due to event hypocenter errors and contamination by a small percentage of erroneous  
431 data. Hypocenter errors are the result of both erroneous data and inaccurate travel time  
432 predictions for radially symmetric Earth models. Unfortunately, making bulletin data useful for  
433 tomographic and other travel time calibration studies is not as straightforward as identifying and  
434 removing large-residual arrival time data; because, single-event locators move the event location  
435 to a position that minimizes all travel time residuals, including an erroneous datum. Therefore,  
436 an erroneous datum may not be evident.

437           Modifications to the *Bayesloc* joint probability formulation of the entire multiple-event  
438 system afford simultaneous reanalysis of all arrival time data. Through MCMC hypothesis  
439 testing, *Bayesloc* captures the range of data, travel time, and hypocenter configurations that peak  
440 overall probability. During MCMC sampling, *Bayesloc* continually explores how the entire  
441 multiple event system responds to the hypothesis that any given datum is incorrectly labeled or  
442 that the datum is erroneous. Therefore, an early assessment that a datum is erroneous does not  
443 preclude reintroduction of the datum under more favorable parameter configurations. This  
444 underscores the probabilistic nature of the *Bayesloc* result and that ambiguity in determining a  
445 phase label, or any other multiple-event parameter, is propagated to the uncertainty of all other  
446 parameters. This gives us confidence in the meaningfulness of high posteriori probability data  
447 labels and in the posteriori assessment of measurement precisions, travel time corrections, and  
448 event hypocenter probability regions.

449 Improved data consistency is exemplified by comparing residuals for nearly reciprocal  
450 paths (Figure 8). Differencing residuals for reciprocal paths reveals significant travel time  
451 inconsistencies for the input (single-event location) data set. Because reciprocal inconsistencies  
452 cannot be attributed to the model error, reciprocal travel time inconsistency is a measure of the  
453 degree to which a tomographic algorithm cannot fit the data. Recent studies demonstrate that  
454 data inconsistencies are not sufficiently mitigated by data averaging [*Husen et al.* 2009; *Diehl et*  
455 *al.* 2009], and data inconsistencies resulting from event mislocation are particularly problematic  
456 for tomography [*Creager and Boyed* 1992].

457 The *Bayesloc* result presented here is used in a companion paper [*Simmons et al.* 201x] to  
458 simultaneously image detailed lithospheric structure in the Middle East as well as broad structure  
459 throughout the mantle. The tomographic study reinforces the accuracy and consistency of the  
460 *Bayesloc* results presented here, as the residual distribution is further reduced by more than a  
461 factor of 2 (variance reduction of 75%) to 0.50 seconds. Lastly, lithospheric structure in the  
462 Middle East is clearly imaged, and the magnitudes of velocity anomalies are significantly larger  
463 than previous studies, despite the low variance of the input data set.

464

#### 465 **Acknowledgments**

466 Funding for this project is provided by the Ground-Based Nuclear Detonation Detection program  
467 (Leslie Casey program manager) within NNSA/NA22. We thank our LLNL colleagues for day-  
468 to-day interactions and support and we thank the broader community for motivation. Thanks also  
469 to Bill Rodi for frequently reminders about the power of travel time reciprocity, as well as wide-  
470 ranging conversations on the location problem.

595 *Bayesloc* mislocation is 4.5 km with epicenter error ellipse area of  $70 \text{ km}^2$ . Single event  
596 mislocation is 10.1 km with epicenter error ellipse area of  $207 \text{ km}^2$ . The satellite location is from  
597 Albright et al., 1998.

598

599 Figure 4. Posteriori precision ( $1/\text{variance}$ ) for phase, station, and event terms. Data precision is  
600 the product of these terms. Phases, stations, and events are ordered from least precise to most  
601 precise. See text for discussion.

602

603 Figure 5. Gaussian representation of posteriori measurement error distribution for each seismic  
604 phase. The 0.42 second shift of  $P_n$  travel prediction is included. Standard deviation of  
605 measurement error for each pick is also tabulated in Table 1.

606

607 Figure 6. Example validation of phase relabeling based comparison with waveform data. In this  
608 case, posteriori labels have probability greater than 0.9. The data shown here are a small subset  
609 of the data for this particular event.

610

611 Figure 7. Input and output (Bayesloc posteriori) residual occurrence as a function of event-  
612 station distance. Input and output residuals are computed using the *ak135* model. Color indicates  
613 the density of residual occurrence on a normalized log scale. See text for discussion.

614

615 Figure 8. Residual difference for approximately reciprocal paths. Solid lines are forward paths  
616 and dashed lines are reciprocal paths. The choice of which path is forward and which is  
617 reciprocal is arbitrary. *Bayesloc* reciprocal travel times are significantly more consistent than the  
618 input data set. All event depths are 20 km or less to minimize path differences near stations.

619 Teleseismic path lengths are  $15^\circ$  to  $95^\circ$  and regional path lengths are  $5^\circ$  to  $15^\circ$ . Maximum  
620 separation between events and stations defining reciprocal-path end points is  $1^\circ$  for teleseismic  
621 paths and  $0.7^\circ$  for regional paths. See for discussion.

622

623 Table 1. Number of picks for each event and summary of posteriori assessment of phase labels.

Phase	Number of picks	Estimated standard deviation	Phase label retained with prob.>0.9	Input label is most probable	Most probably erroneous.
P	817,552	0.74 s	92%	96%	0.6%
Pn	42,327	0.90 s	90%	98%	0.2%
pP	10,524	1.60 s	90%	95%	2.1%
sP	4,992	2.22 s	92%	97%	2.6%
PcP	3,140	1.83 s	96%	98%	1.6%

624

625

626 Table 2. Prior constraints (standard deviation). Priors not listed are uninformative (broad).

	Travel Time Curves		Event Depth	Correct Phase Label input
	Shift	Slope		
P	$10^{-6}$ s	5 s/degree		0.9
Pn	5 s	5 s/degree		0.9
pP	$10^{-6}$ s	5 s/degree		0.9
sP	$10^{-6}$ s	5 s/degree		0.9
PcP	$10^{-6}$ s	5 s/degree		0.9
EHB events with depth>70 km			5 km
