## 31 **Introduction**

32 Gas hydrates are clathrate structures of H<sub>2</sub>O that encage gases of small molecular  
33 diameter, such as methane, ethane, propane, CO<sub>2</sub>, etc. [*Sloan and Koh, 2007*]. The formation of  
34 gas hydrates typically requires moderately low temperatures, high pressure, and sufficient  
35 quantities of water and free- or dissolved-phase hydrate-forming gas. Such conditions occur  
36 globally – and often extensively – in permafrost regions and shallow marine environments such  
37 as in seafloor sediments along continental margins [*Kvenvolden and Lorensen, 2001*].  
38 Consequently, gas hydrates are very common in these regions and harbor a significant  
39 hydrocarbon source that is of keen interest for economic as well as geohazard considerations  
40 [e.g., *Kvenvolden, 1999; Collett, 2002; Ruppel, 2007, Maslin et al., 2010, Boswell and Collett,*  
41 *2011*]. Estimates of the total global hydrate inventory have varied by up to four orders of  
42 magnitude [e.g., *Kvenvolden, 1999; Milkov, 2004*], with more recent estimates predicting that the  
43 amount of carbon bound by gas hydrates is greater than the total amounts in the atmosphere plus  
44 conventional natural gas reserves [*Boswell and Collett, 2011; Wallman et al., 2012*]. Estimates  
45 continue to improve with significant advances in global modeling and geophysical mapping of  
46 gas hydrate inventories [*Maslin et al., 2010; Boswell and Collett, 2011*].

47 Traditional methods for geophysical detection of gas hydrates include well-logging and  
48 seismic surveys. Well-logging provides point measurements of gas hydrate concentration versus  
49 depth, but is expensive and invasive. Seismic methods are also used to map the spatial  
50 distribution of gas hydrate deposits. The presence of a bottom simulating reflector (BSR) may  
51 indicate the phase boundary between gas hydrate and free gas [e.g., *Hornbach et al., 2003*]. This  
52 boundary alone, however, provides little information about the amount and distribution of gas  
53 hydrate above it. Seismic blanking zones can be used in some cases to help predict gas hydrate

54 occurrence [e.g., *Hornbach et al.*, 2003; *Zhang and McMechan*, 2006]. Additional geophysical  
55 methods are clearly needed to obtain a more complete picture of gas hydrate distribution.

56         Electrical methods can be effective in remotely detecting gas hydrate due to the  
57 sensitivity of electrical properties to the compositions and microstructures of sedimentary  
58 materials [*Edwards*, 1997]. Gas hydrates have low electrical conductivity ( $\sigma$  – note that this is  
59 the inverse of resistivity:  $\rho = \sigma^{-1}$ ) that provides a suitable target for marine controlled source  
60 electromagnetic (CSEM) surveys. CSEM sounding measures the amplitude and phase of  
61 electromagnetic (EM) energy through the seafloor at one or more frequencies, and this data can  
62 be inverted to obtain the spatial distribution of conductivity. The combined use of both seismic  
63 and EM methods can help distinguish between gas (low velocity, high resistivity) and gas  
64 hydrate (high velocity, high resistivity), to map both the upper and lower boundaries of gas  
65 hydrate deposits. Pilot CSEM studies have demonstrated the sensitivity of this method in  
66 assessing general gas hydrate concentration, saturation, and distribution patterns [e.g.  
67 *Schwalenberg et al.*, 2005; *Evans*, 2007; *Weitemeyer et al.*, 2006, 2011]. Quantifying the  
68 estimates of hydrate volume, however, requires knowledge of the electrical conductivity of gas  
69 hydrates in combination with petrophysical mixing relations established from theory and  
70 experiment [*Collett and Ladd*, 2000; *Ellis et al.*, 2008].

71         Several previous laboratory studies focused on the electrical properties of gas hydrates in  
72 mixtures with sediment and water [*Spangenberg and Kulenkampff*, 2006; *Lee et al.*, 2010; *Ren et*  
73 *al.*, 2010]. The electrical conductivity of CH<sub>4</sub> hydrate was measured during formation from liquid  
74 water in the pore space of glass beads [*Spangenberg and Kulenkampff*, 2006] and quartz sand  
75 [*Ren et al.*, 2010]. A similar study examined electrical conductivity before and after gas hydrate  
76 formation within sandy sediments, using brine with 3.35 wt% NaCl [*Li et al.*, 2012]. These

77 measurements are important for helping resolve mixing laws, but they are dominated by the  
78 presence of water, which obscures quantitative information on the more subtle contributions by  
79 gas hydrate or sediments to the overall electrical conductivity. Geometrical mixing laws, such as  
80 Archie's law or Hashin-Shtrikman lower bounds models can be used with the assumption that  
81 gas hydrate has low  $\sigma$  compared to the surrounding seawater [*Archie, 1942; Hashin and*  
82 *Shtrikman, 1962; Glover et al., 2000*]. This assumption is valid when the conductive pore water  
83 phase dominates the bulk conductivity – which is in fact the common mode in nature – but may  
84 not be valid where gas hydrate (the low conductivity phase) occurs in massive form or otherwise  
85 dominates bulk conductivity. The latter case can be especially important for mapping hydrate  
86 formations that are impermeable to gas, as they may also be relatively impermeable to pore water  
87 [e.g., *Kneafsey et al., 2011*]. *Lee et al.* [2010] published a systematic examination of electrical  
88 conductivity and permittivity (electric field response) for water-free tetrahydrofuran (THF)  
89 hydrate mixed with sand, silts, and clay, but as THF hydrate is only an analog for natural gas  
90 hydrate, it may have different conduction mechanisms due to its different molecular structure as  
91 a structure II (sII) hydrate versus the more common naturally occurring structure I (sI) hydrate.

92       Lastly, the previous studies have not carefully examined the temperature dependence of  
93 the electrical conductivity gas hydrate/sediment mixtures. Most electrical insulators, such as gas  
94 hydrates, have electrical conductivity that increases exponentially with increasing temperature.  
95 Details of this relationship can yield important mechanistic information about conduction  
96 mechanisms [e.g., *Roberts, 2002*], which must be understood to properly apply laboratory  
97 measurements to the widely varying conditions that exist in the field.

98       *Du Frane et al.* [2011] recently published the first direct measurements of the electrical  
99 conductivity of single-phase CH<sub>4</sub> hydrate formed from reacting high purity H<sub>2</sub>O and CH<sub>4</sub>. The  $\sigma$

100 of CH<sub>4</sub> hydrate ranged between 10<sup>-5</sup> to 10<sup>-4</sup> S/m for temperatures between -15 and 15 °C,  
101 indicating strong, positive temperature dependence. These results were obtained in a custom-  
102 built pressure cell designed to allow synthesis of increasingly complex gas hydrate + sediment ±  
103 water mixtures, in which electrical conductivity can be measured *in situ* during both formation  
104 and dissociation of the hydrate phase. This method allows for controlled and pre-determined  
105 mixing and textural arrangement of the various components in the system, meaning that the  
106 effects of individual components can be assessed for better integration into mixing models. In  
107 this study, we present new electrical conductivity results for the 2-component system of fully  
108 reacted (i.e. water-free) methane hydrate in mixtures with varying proportions of sediments  
109 (quartz sand and glass beads) for a range of temperatures between -15 to 15 °C.

110         We note that many – if not most – gas hydrate systems in nature contain a pore water  
111 component that dominates the overall electrical properties of the system, hence results from  
112 multi-component samples that include a pore water phase will obviously be critical for modeling  
113 most systems in nature. However, massive gas hydrate formations that are lacking in pore water  
114 are expected to be present in some locations in nature, and such units could be of high economic  
115 value. Measuring electrical conductivity of mixed-phase systems in which there is no knowledge  
116 of the competing effects of the separate components, how the various components are positioned  
117 or connected within the system, or in what manner individual conduction mechanisms influence  
118 total conductivity, would simply yield isolated and ambiguous measurements due to the  
119 numerous unknowns. Also, the more subtle effects of adding sediment to gas hydrate would be  
120 eclipsed when adding an additional free water phase, and the only way to investigate such effects  
121 is by careful measurement of liquid-free systems. Future experiments are anticipated to

122 incorporate a free water phase into the system in order to help develop the more complex models  
123 relevant to most natural systems.

#### 124 **Experimental Techniques**

125 We developed a cell to synthesize gas hydrate and simultaneously measure electrical  
126 conductivity (Fig. 1). The apparatus is built around a commercially available pressure vessel  
127 (High Pressure Equipment Company) with the addition of high pressure manifolds on each end-  
128 cap. Each manifold has a single port feed-through where methane gas and electrical leads enter  
129 into the vessel. Samples were 2.0” in diameter and 0.5” thick, and were sandwiched by silver  
130 electrodes and Teflon spacers. Methane hydrate was synthesized in the pressure cell using a  
131 temperature cycling technique that enables full reaction of H<sub>2</sub>O ice “seeds” and pressurized CH<sub>4</sub>  
132 (15-30 MPa) to polycrystalline CH<sub>4</sub> hydrate in a reproducible manner [*Stern et al.*, 1996, 2004].  
133 The reactant ice seeds were made from a block of nearly gas-free ice that was grown from  
134 distilled-deionized water, then crushed and sieved to 0.180-0.250 mm.

135 Starting samples were prepared from granular ice that was free of sediment, mixed with  
136 quartz sand, or mixed with silica glass beads. The OK#1 sand and glass beads were not washed  
137 prior to use. Mixtures were made in proportions ranging from pure (100 %) ice down to 10 vol%  
138 ice, and 0-90 vol% sand or beads, with percentages referring to the solid phase only. All samples  
139 initially contained ~30-40% porosity, determined from mass measurements of each phase prior  
140 to mixing and packing into the known-volume sample chamber. Ice-only samples had highest  
141 initial porosity given their relatively uniform grain size compared to mixed-phase samples. In all  
142 samples, porosity reduces during reaction due to the ~ 16% volumetric increase of the H<sub>2</sub>O  
143 phase that accompanies the ice to hydrate reaction, assuming density of ice and an empty sl  
144 hydrate lattice to be 917 and 790 kg/m<sup>3</sup> respectively [*Dvorkin et al.*, 2000]. Porosity of final

145 samples is thus easily calculated, and the issue of porosity has been discussed previously in *Du*  
146 *Frane et al.* [2011]. For mixtures with sand, we used Oklahoma #1 (OK #1) high-purity quartz  
147 ( $\text{SiO}_2$ ) sand that had minor hematite, illite, calcite, and alumina (< 1 vol % combined), and a  
148 narrow grain size distribution with 84% of grain diameters between 0.106 to 0.250 mm [*Durham*  
149 *et al.*, 2009]. Two sample mixtures contained glass beads (Cataphote) made of high-purity soda-  
150 lime-silica (amorphous  $\text{SiO}_2$  with a small amount of  $\text{Na}_2\text{CO}_3$  [*NIIR Board of Consultants &*  
151 *Engineers*, 2005]) glass with diameters ranging between 0.105 to 0.125 mm. Sample mixtures  
152 and run conditions are listed in Table 1.

153         The cell was first loaded with seed ice  $\pm$  sediments and placed under methane pressure in  
154 a temperature controlled bath of inert coolant, d-Limonene. Heating the reactants above the ice  
155 point to conditions well within the methane hydrate stability field promoted full and efficient  
156 reaction to hydrate. The first run was carried out with one manifold replaced by a thermocouple,  
157 to calibrate and monitor the synthesis reaction; any unreacted  $\text{H}_2\text{O}$  remaining after the heating  
158 stage was easily discernible by a discontinuity in the pressure-temperature curve upon cooling  
159 the sample below the ice point, in which case additional heating cycles were implemented.  
160 Subsequent runs were then performed without a thermocouple in the sample, using the  $\sigma$   
161 measurement itself as an indicator of complete reaction, as it was similarly sensitive to excess  
162 liquid when cycling past the freezing/melting point. Samples were cycled multiple ( $\geq 7$ ) times to  
163 ensure full reaction. During experiments, temperature and electrical conductivity were monitored  
164 and recorded throughout formation, stabilization, and dissociation.

165         Impedance spectroscopy data (20 Hz to 2 MHz) were collected with an Agilent E4980A  
166 LCR (inductance, capacitance, and resistance) meter throughout each run. The spectra were used  
167 to determine what frequency impedance measurement is needed to calculate the true electrical

168 conductivity of the sample while excluding systemic contributions [*e.g. Roberts et al.*, 1991;  
169 1993]. It should be noted that the range of frequencies swept during impedance spectroscopy  
170 measurements in the lab are unrelated to the frequencies used in CSEM field measurements. Our  
171 previous equivalent circuit modeling [*Du Frane et al.*, 2011] indicates that conductivity can be  
172 measured reliably at the frequency associated with the smallest capacitance to isolate the  
173 electrical response of our samples and avoid systemic effects, such as electrode polarization at  
174 low frequency. Measurements were performed on samples with fully-reacted CH<sub>4</sub> hydrate  
175 between -15 to 15 °C after 7 or more automated temperature cycles. Heating was isochoric such  
176 that the pore pressure of CH<sub>4</sub> gas increased during the measurement (pressure ranges are listed in  
177 Table 1). Comparative impedance measurements were also performed between -15 to -2 °C on  
178 several samples after the CH<sub>4</sub> hydrate was dissociated back into ice by venting CH<sub>4</sub> from the  
179 vessel at temperatures  $\leq -3$  °C for  $\geq 6$  days (Table 1). Single frequency electrical conductivity  
180 (typically at 100 kHz) was monitored during CH<sub>4</sub> hydrate synthesis and dissociation to verify  
181 completion of each reaction. We also monitored sample conductivity after each incremental  
182 heating step to ensure that samples had re-equilibrated to each new temperature before  
183 performing broad-band measurements used to calculate electrical conductivity.

184       Samples containing either CH<sub>4</sub> hydrate or ice were recovered for cryogenic scanning  
185 electron microscope (cryo-SEM) analysis. To recover samples with CH<sub>4</sub> hydrate, the vessel was  
186 cooled sufficiently with liquid nitrogen (LN) prior to depressurization. CH<sub>4</sub> hydrate samples were  
187 then stored and transported in LN to a cryo-preparation station and imaging stage (Gatan Alto  
188 Model 2100) that in turn attached directly to a LEO982 field emission SEM. Samples were  
189 cleaved under vacuum in the preparation station to produce fresh surfaces uncontaminated by  
190 water condensation, and then transferred under vacuum into the SEM column. A thermocouple

191 embedded in the SEM sample stage recorded temperature throughout the imaging process.  
192 Imaging was conducted at temperature  $< -185$  °C, vacuum  $< 10^{-6}$  kPa, and accelerating voltage  $\leq$   
193 2 kV. Further details of cryo-SEM imaging techniques and instrumentation are given in *Stern et*  
194 *al.* [2004]. Sample material was destroyed in the process of SEM imaging due to the high  
195 vacuum environment.

## 196 **Results**

### 197 *Cryogenic scanning electron microscopy*

198 Cryo-SEM images verified that the synthesized gas hydrate was fully-reacted  
199 polycrystalline CH<sub>4</sub> hydrate (Fig. 2). Sample porosity is greatly reduced in the final material due  
200 to the volumetric increase accompanying the ice to gas hydrate reaction, resulting in primarily  
201 isolated macro-pores (Fig. 2A). Images verified that grain-scale characteristics were in general  
202 reproducible across all samples, with individual grains ranging from 10-80  $\mu\text{m}$  in diameter. CH<sub>4</sub>  
203 hydrate grains were fully dense as grown (Fig. 2A and inset), but surface pitting developed  
204 within several minutes of imaging in the high-vacuum column (Fig. 2B and inset). OK#1 and  
205 glass bead sediments were uniformly distributed in mixed samples (Fig 2C-F), thereby  
206 establishing a basis for comparison of  $\sigma$  measurements between mixed-phase runs. Despite  
207 annealing of ice grains accompanying dissociation, SEM images also indicated no significant  
208 migration of sediments during any given run, thus enabling comparison of  $\sigma$  measurements  
209 before, during, and after dissociation within a single run. The hydrate or ice grains appear to be  
210 well connected in all samples except for the one with 10:90 vol% ice:sand (Fig. 2F). We were  
211 unable to evaluate subtle textural changes due to the effects of sublimation during cryo-SEM  
212 analyses. It has been previously established that our formation techniques result in samples with  
213 consistent texture, having undergone multiple cycles through the ice point with lengthy holds at

214 the peak temperatures well above 0°C that allows samples to anneal [*Stern et al.*, 2004]. The  
215 texture of the methane hydrate in samples mixed with sand also resembles textures observed in at  
216 least some hydrate-bearing sands retrieved from nature, such as from the Alaska North Slope  
217 [*Stern et al.*, 2011].

### 218 ***Electrical Conductivity***

219 The H<sub>2</sub>O was verified to be fully-reacted to CH<sub>4</sub> hydrate within several temperature  
220 cycles, consistent with previous studies [e.g., *Stern et al.*, 1996; 2004]. Impedance spectra were  
221 then collected on samples while heating incrementally from -15 to 15 °C, with samples  
222 undergoing 7-16 temperature cycles total during the full run (Table 1). At each temperature  
223 increment, samples typically required ~1 hour to re-equilibrate before electrical conductivity  
224 could be measured due to the low thermal conductivity/ diffusivity of the samples [e.g., *Waite et*  
225 *al.*, 2007].

226 The addition of sediment complicated the interpretation of impedance spectra of the CH<sub>4</sub>  
227 hydrate. Equivalent circuit modeling of these spectra was not feasible due to the noisiness of  
228 impedance magnitude data measured at frequencies > 500 kHz and < 1 kHz (Fig. 3A).  
229 Equivalent circuit modeling by *Du Frane et al.* [2011] for sediment-free samples indicated that  
230 the impedance magnitude associated with the maximum phase angle could be used to avoid  
231 systemic effects due to the electrodes and their leads (see Fig. 3A in *Du Frane et al.* [2011]). For  
232 CH<sub>4</sub> hydrate mixed with sediments, the phase angle data show maxima at intermediate  
233 frequencies on the order of ~100 kHz similar to pure CH<sub>4</sub> hydrate samples (Fig. 3B). This was  
234 also the case after dissociation of CH<sub>4</sub> hydrate to ice (Fig. 3C and 3D). Based on these  
235 observations, we similarly used phase angle to determine the correct frequency to calculate  
236 electrical conductivity.

237 Electrical conductivity of mixtures generally exhibited exponential dependence on  
238 temperature both after CH<sub>4</sub> hydrate formation, and after dissociation to ice, which is typical for  
239 electrolytic materials. We fit data using an Arrhenius expression,

$$240 \quad \sigma(T) = \sigma_0 e^{-E_a/RT} \quad (1)$$

241 where  $\sigma_0$  is a pre-exponential constant (S/m),  $E_a$  is activation energy (kJ/mol),  $R$  is the gas  
242 constant (8.314 J/mol/K), and  $T$  is temperature (K). Plotting  $\text{Log}(\sigma)$  versus  $10^3/T(\text{K})$  gives slopes  
243 that are proportional to  $E_a$  (Fig. 4). Table 1 gives fitted parameters for  $\sigma_0$  and  $E_a$  for each sample  
244 mixture that can be used to calculate electrical conductivity as function of temperature.

245 Increased sand concentrations of up to ~45 vol% in mixtures with CH<sub>4</sub> hydrate resulted in  
246 increased conductivity of the overall mixtures (runs 4, 5, 6, and 8; Table 1, Fig. 4). Conversely,  
247 the sample with 10:90 vol% CH<sub>4</sub> hydrate:sand (run 10) had much lower conductivity. SEM  
248 images indicate that dissociated ice, and likely CH<sub>4</sub> hydrate, was poorly connected in this sample  
249 (Fig. 2F), in which case surface conductivity through the well-connected sand may have a non-  
250 negligible contribution to the electrical conductivity of the mixture [e.g., *Wildenschild et al.*,  
251 2000; *Revil et al.*, 2014]. Activation energy decreased substantially with increasing sand, from  
252 30.6 kJ/mol for pure CH<sub>4</sub> hydrate to 7.66 kJ/mol for a sample containing ~45 vol% sand. The  
253 CH<sub>4</sub> hydrate + sand mixtures showed little  $\sigma$  change as we vented CH<sub>4</sub> to approach the edge of  
254 the stability field (Fig. 5A), indicating that the effects of pressure are small in the range of these  
255 experiments. Once the CH<sub>4</sub> gas was fully vented, electrical conductivity slowly began to increase  
256 as the CH<sub>4</sub> hydrate in samples dissociated to ice (Fig. 5B). The presence of sand produced  
257 similar  $\sigma$  increases after dissociation of CH<sub>4</sub> hydrate to ice, but had less effect on  $E_a$ .

258 Two experiments (runs 7 and 9) were conducted using ~ 45 vol% glass beads of similar  
259 grain size as OK#1 for comparison to runs with sand. Run 9 showed that glass beads had less

260 overall effect on electrical properties of CH<sub>4</sub> hydrate than sand (Fig. 4); mixing glass beads into  
261 CH<sub>4</sub> hydrate led to only a slight increase in overall electrical conductivity and a slight decrease in  
262 activation energy. The glass beads are less angular, and consequently will have less connectivity  
263 than sand for a given volume percentage. However, SEM images (Fig. 2C and 2E) indicate that  
264 both sand and glass beads are well-connected at ~45 vol%. Small differences in connectivity past  
265 the percolation threshold are unlikely to account for the substantially larger effects that sand has  
266 on electrical conductivity of mixtures with CH<sub>4</sub> hydrate relative to glass beads (Fig. 4), but  
267 further studies are needed to fully evaluate the effects of angularity and grain orientation. Ion  
268 chromatography (IC) and total inorganic carbon (TIC) analyses conducted on select samples that  
269 were dissociated after testing (runs 3, 5, 6, and 7) verified that significant amounts of ionic  
270 impurities were present on the surfaces of both the sand and glass beads (data presented in  
271 Supporting Information).

## 272 **Discussion**

273 Electrical conductivity measurements on water-free CH<sub>4</sub> hydrate + sediment mixtures in  
274 this study are predictably lower in magnitude than those previously reported for water-bearing  
275 mixtures [*Spangenberg and Kulenkampff* 2006; *Ren et al.*, 2010; *Li et al.*, 2012]. The  $\sigma$  of CH<sub>4</sub>  
276 hydrate with ~45 vol% quartz sand (OK#1) is 1 order of magnitude lower than a measurement of  
277  $10^{-2.42}$  S/m reported for 62 vol% glass beads packs saturated with 36 vol% CH<sub>4</sub> hydrate and 2  
278 vol% water [*Spangenberg and Kulenkampff* 2006]. Measurements on sand packs saturated with  
279 ~10 vol% CH<sub>4</sub> hydrate and ~20 vol% water are on the order of  $10^{-0.5}$  S/m at 5 °C [*Ren et al.*,  
280 2010], significantly higher than measurements on water free mixtures.

281 Unexpectedly, the addition of sediment in the form of quartz sand and glass beads  
282 increased the overall electrical conductivity of most sample mixtures with CH<sub>4</sub> hydrate or ice

283 (Fig. 4). This is somewhat counterintuitive because quartz sand and silica beads by themselves  
284 have low electrical conductivity. The one exception was the mixture with 90 vol% sand that had  
285 significantly lower electrical conductivity than other sample mixtures. Ice appeared poorly  
286 connected within this mixture in SEM images (Fig. 2F), suggesting that this high concentration  
287 of sand exceeds the percolation threshold (i.e. the concentration required for connectivity) for  
288 both the dissociated ice and CH<sub>4</sub> hydrate. This indicates that the CH<sub>4</sub> hydrate or ice grains  
289 provided the primary path for current when connected through sample mixtures, although the  
290 presence of sediment raised total electrical conductivity. The increase to electrical conductivity  
291 by the presence of ~45 vol % glass beads was significant (run 9), but substantially lower than the  
292 effects of naturally weathered quartz sand (Fig. 4).

293         Electrical conductivity was likely enhanced in the CH<sub>4</sub> hydrate grains by impurities that  
294 were introduced from weathered surfaces of the sand. Ionic doping of the CH<sub>4</sub> hydrate grains  
295 could explain why activation energies decreased with increased sand concentrations. The  
296 activation energy contains two physical phenomena: an increase in defect mobility with  
297 temperature and an increase in defect population with temperature. These impurities are likely to  
298 have low mobility but are charge-compensated by protonic defects that have relatively high  
299 mobility. When there are few to no impurities present, protonic defects are likely to be thermally  
300 induced in the gas hydrate structure, which would make electrical conductivity strongly  
301 dependent on temperature. If the structure is doped with impurities there could be a population of  
302 protonic defects induced to maintain charge balance that are relatively insensitive to temperature.  
303 Doping would cause electrical conductivity to increase substantially with a population of charge  
304 carriers that mask those that are thermally induced, yielding electrical conductivity with less  
305 temperature dependence, i.e. lower activation energy. The electrical conductivity of CH<sub>4</sub> hydrate

306 + sand mixtures was substantially higher than pure CH<sub>4</sub> hydrate (Fig. 4), which indicates that  
307 some impurities from sand can be included in CH<sub>4</sub> hydrate. Probable candidates include ions that  
308 were found in higher concentrations on the surfaces of the sand compared with those on the  
309 surface of glass beads: K<sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>, NH<sub>4</sub><sup>+</sup>, Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup> (Table S1 in Supporting Information).  
310 Most impurities that are dissolved in water become excluded during ice crystallization, with the  
311 exception of a few acids (HF, HCl), ammonia (NH<sub>3</sub>), alkalis (KOH, NaOH) and their derivatives  
312 (NH<sub>4</sub>F or KCl) that drastically change the protonic carrier concentration [e.g., *Petrenko and*  
313 *Whitworth*, 1999]. KOH inclusion into THF hydrate has also been demonstrated to trigger  
314 formation of charge carriers, Bjerrum and protonic defects, and could also affect mobilities of  
315 other point defects [*Nelson et al.*, 2013]. If CH<sub>4</sub> hydrate behaves similar to ice, then the sand may  
316 have contributed KOH and its derivative KCl during synthesis, which is consistent with IC  
317 detection of both K<sup>+</sup> water melted from samples containing sand (runs 5 and 6), but not in those  
318 containing glass beads (run 7) or in those that did contain any sediment (run 3) (Table S1). It  
319 would also be expected that NaCl and Na<sub>2</sub>CO<sub>3</sub> would be excluded during its crystallization.  
320 Inclusion of K<sup>+</sup> and Cl<sup>-</sup> is thus one possible explanation for what caused the observed doping  
321 effect on the electrical conductivity of CH<sub>4</sub> hydrate-sand mixtures.

322 A first-order model of the doping effect on the electrical conductivity of CH<sub>4</sub> hydrate and  
323 ice caused by impurities from sand is presented in Supporting Information section S2. The  
324 model includes a second conductivity term that is proportional to sand concentration, and  
325 assumes a simple parallel mixing law relationship. We were able to obtain excellent fits to data  
326 for sample mixtures with 10 or 30 vol% sand, but not for those with ~45 or 90 vol% sand. This is  
327 because mixing laws are typically incapable of expressing behavior across percolation  
328 thresholds. If impurities do not move far from the sand surface, CH<sub>4</sub> hydrate/sand interfaces may

329 have higher electrical conductivity than the bulk conductivity of CH<sub>4</sub> hydrate grains. If both CH<sub>4</sub>  
330 hydrate and sand are interconnected, then interfaces between the two phases will also be  
331 interconnected possibly creating a high conductivity path throughout mixtures. This could  
332 explain the large increase in electrical conductivity and decrease in activation energy when  
333 increasing the amount of sand in mixtures from 30 to ~45 vol%. Therefore, the model is only  
334 applicable to scenarios where hydrate/ice is well connected in mixtures, but the sediment is not,  
335 and should be considered preliminary at best given the limited range of compositions examined  
336 here.

337         The results of this study imply that sediment composition, in addition to sediment amount  
338 and distribution, will be a critical factor in determining bulk electrical conductivity of gas  
339 hydrates, at least in sections devoid of pore water. In nature, impurities could be acquired from  
340 sediments, organic material, or pore water itself. While gas hydrate formation is typically viewed  
341 as a purification process – a promising aspect that can potentially be exploited for desalination of  
342 highly saline waste water into potable water [*Cha and Seol*, 2013] – our results suggest that even  
343 trace amounts of impurities incorporated within the CH<sub>4</sub> hydrate lattice produce substantial  
344 effects on the overall electrical properties of CH<sub>4</sub> hydrate. The OK#1 and glass beads were  
345 chosen for this study because they are regarded to have high purity in comparison to most  
346 sediment and facilitated our attempt to study the fundamental contributions of individual  
347 conduction mechanisms to total conductivity. In contrast, sediments found in permafrost and  
348 marine settings have the potential to contribute different and larger concentrations of impurities.  
349 Pore water may also contribute impurities in amounts substantial enough to affect the electrical  
350 properties, although this effect would likely be masked in comparison with the effect of the pore  
351 water itself. For example, seawater contains roughly 400 mg/L of K<sup>+</sup> [*Webb*, 1939], which is

352 within the range of measured values for water melted from the post-run samples (Table S1).  
353 Physical and chemical conditions will also play a role in what concentrations of impurities are  
354 included during gas hydrate formation. Chemical transfer of ionic impurities must be carefully  
355 considered to accurately determine the electrical conductivity of gas hydrate formations in  
356 marine sediments.

### 357 **Conclusions**

358 The electrical conductivity of liquid-free CH<sub>4</sub> hydrate-sediment mixtures is highly  
359 dependent on composition and temperature. Increasing sand concentrations up to 45 vol%  
360 increased the overall electrical conductivity of mixtures by as much as an order of magnitude at  
361 0 °C. The overall electrical conductivity of mixtures plummeted in a sample containing a  
362 sufficiently high sediment concentration (90 vol%) that crossed percolation threshold, such that  
363 the CH<sub>4</sub> hydrate was poorly connected. This observation provides evidence that CH<sub>4</sub> hydrate  
364 (and ice after dissociation) is the primary current path within mixtures.

365 Ionic impurities from sand caused a doping effect on the electrical properties of CH<sub>4</sub>  
366 hydrate (and ice). This is consistent with the observation that increasing sand content in mixtures  
367 resulted in higher magnitude electrical conductivity and less temperature dependence, i.e. lower  
368 activation energy values. Over the range of geologically-relevant temperatures from -5 to 15 °C,  
369 the overall electrical conductivity of CH<sub>4</sub> hydrate mixtures with ≤ 30 vol % sand increased by  
370 ~3 times. Mixtures with ≥ 45 vol% CH<sub>4</sub> hydrate exhibited almost no change in conductivity over  
371 that same range. Most of the ionic impurities associated with the glass beads appear to have been  
372 excluded during CH<sub>4</sub> hydrate formation (Na<sup>+</sup>, CO<sub>3</sub><sup>2-</sup>, HCO<sub>3</sub><sup>-</sup>), while at least some of the ionic  
373 impurities more strongly associated with the sand grains were included (K<sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>, NH<sub>4</sub><sup>+</sup>,  
374 Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>).

375           The addition of sediments to samples is the methodical 2<sup>nd</sup> step in the evolution of this  
376 work, following our initial measurements of pure, end-member CH<sub>4</sub> hydrate. While these results  
377 can only be loosely applied to “dry” systems with essentially no pore water present, they are  
378 necessary experiments to increase the fundamental understanding of individual conduction  
379 mechanisms and the properties of mixtures in these systems. Future tests involving the  
380 controlled addition of liquid water with varying salinities will be necessary for further  
381 application to complex natural systems.

506 <sup>a</sup>Excludes porosity.

507 <sup>b</sup>Data from *Du Frane et al.*, 2011.

508

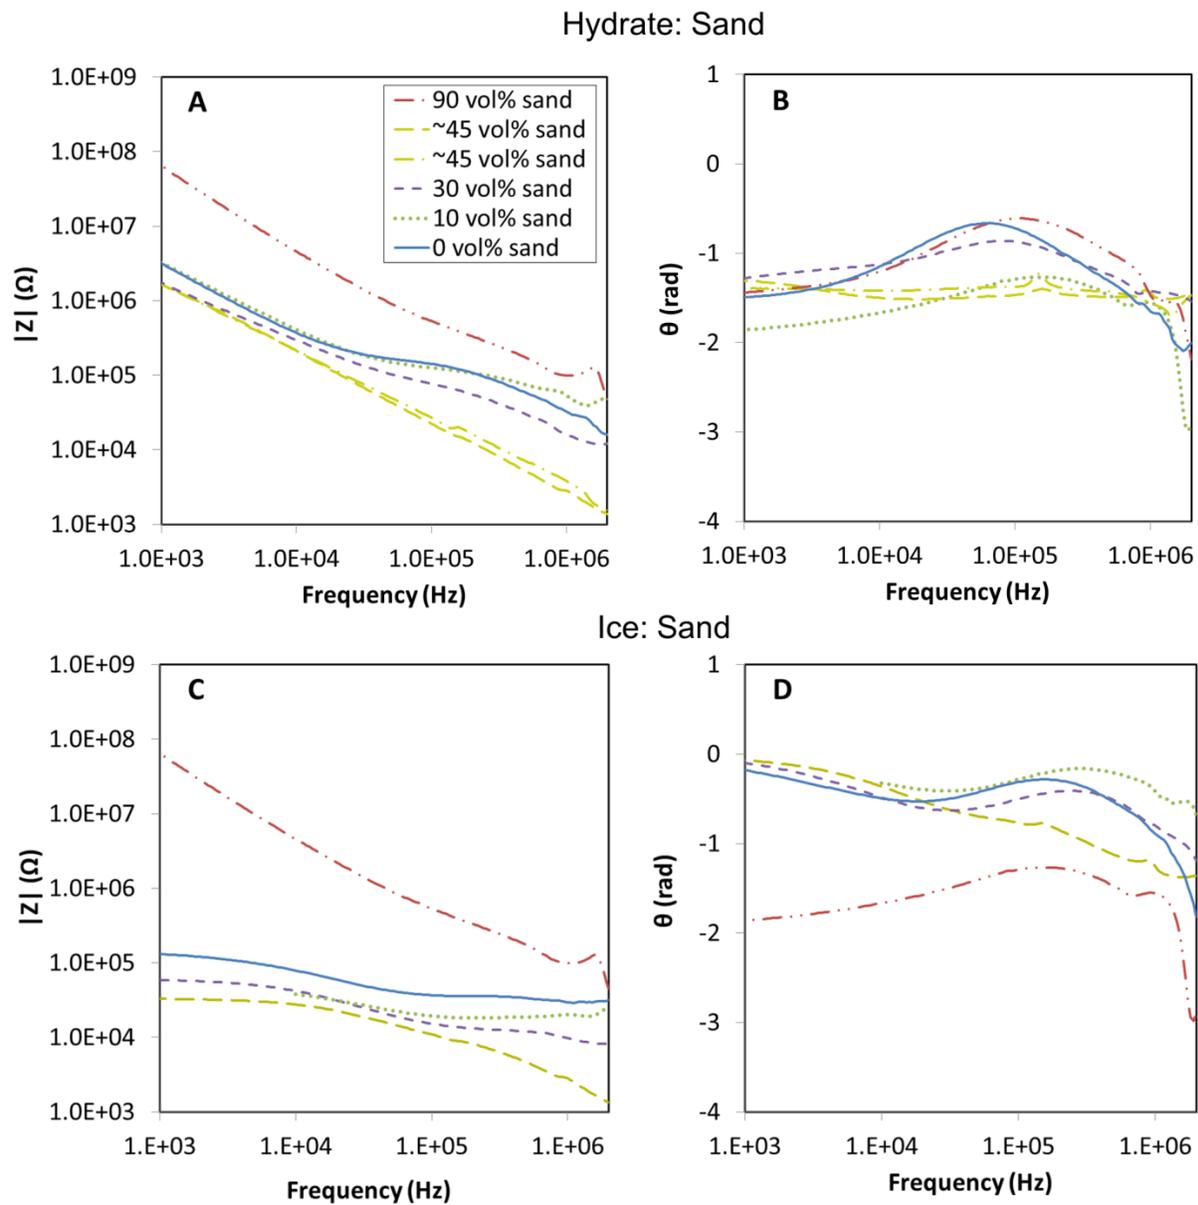

509 **Figure 1.** Pressure vessel designed to synthesize gas hydrate and measure impedance510 spectroscopy *in situ* [from *Du Frane et al.*, 2011].

511

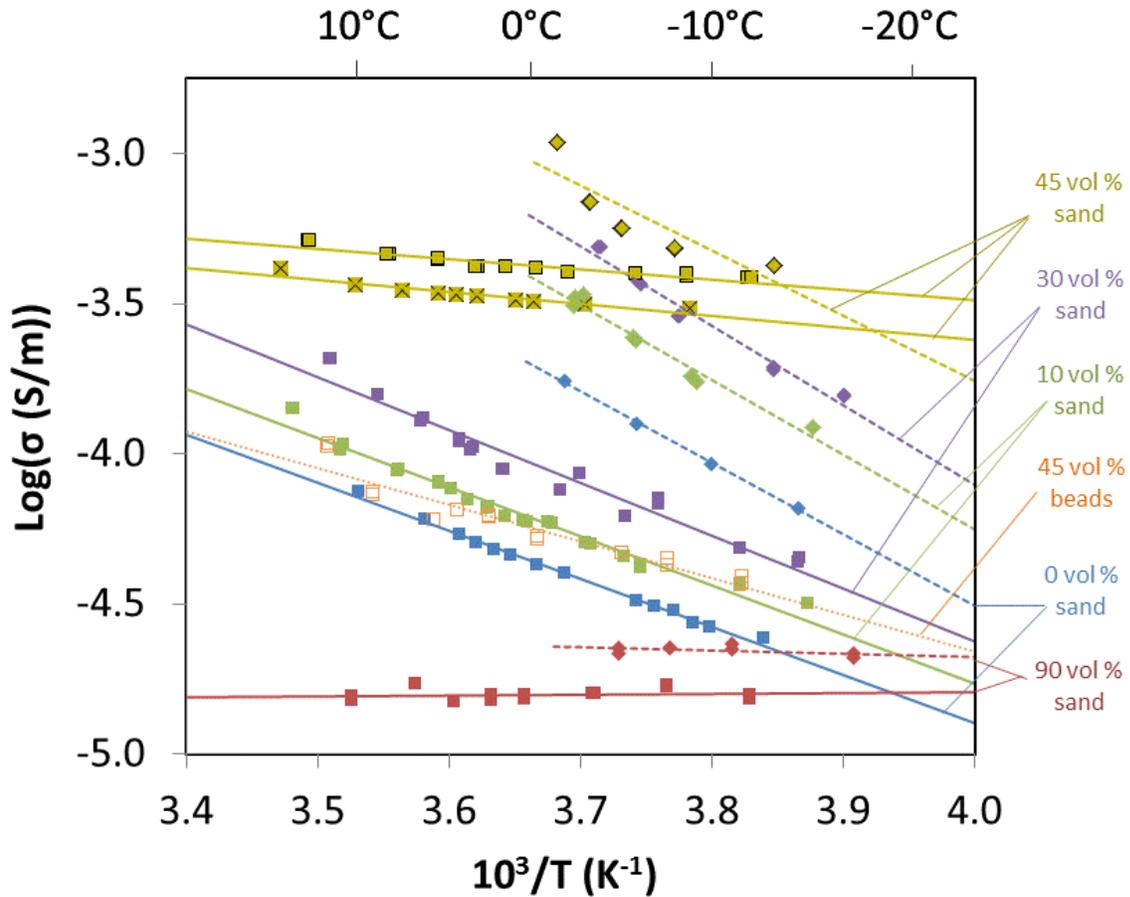

512

513 **Figure 2.** Cryo-SEM images of CH<sub>4</sub> hydrate and hydrate-sediment mixtures. Single-phase  
514 polycrystalline CH<sub>4</sub> hydrate had ~20% porosity, grain size diameters of 10-80 microns, and were  
515 fully dense as-grown (A, inset), but developed surface pitting with time in the high-vacuum SEM  
516 column, which resulted in a nano- or meso-porous surface texture (B, inset). C shows a  
517 ~55:45vol% hydrate:sand sample (Run 4) and D shows a ~55:45vol% ice:sand sample (Run 8).  
518 Significant annealing of the ice grains accompanies dissociation at our test conditions (compare  
519 D and C insets), but there is no significant migration of sand, thus enabling comparison of  
520 measurements before and after dissociation. E shows a 55:45vol% hydrate:beads sample (Run 9).  
521 SEM shows uniform distribution of phases in all three samples (C, D, and E) as well as  
522 similarities in the nature of the grain contacts, helping establish a basis for comparison of  
523 conductivity measurements. The pitting and more porous appearance of 2E is a result of  
524 sublimation of gas hydrate under high-vacuum conditions in the FE-SEM column, which is  
525 accentuated in samples with higher sediment content due to higher surface-to-volume ratio of the  
526 hydrate phase [Stern *et al.*, 2004]. F shows a 10:90vol% ice:sand sample (Run 10), with  
527 connecting ice expanded in the inset. In D and F, the samples are more porous than A-C because  
528 the hydrate-to-ice dissociation reaction results in a ~16% volumetric reduction of the H<sub>2</sub>O phase,  
529 as discussed in text.

530

531 **Figure 3.** Total impedance magnitude ( $|Z|$ ) and phase ( $\theta$ ) data as a function of frequency  
 532 collected for  $\text{CH}_4$  hydrate: sand mixtures (A, B), and ice: sand mixtures after dissociation of  $\text{CH}_4$   
 533 (C, D). Data are plotted for  $\text{CH}_4$  hydrate/ice without sediment as a solid blue line [Du Frane et  
 534 al., 2011].

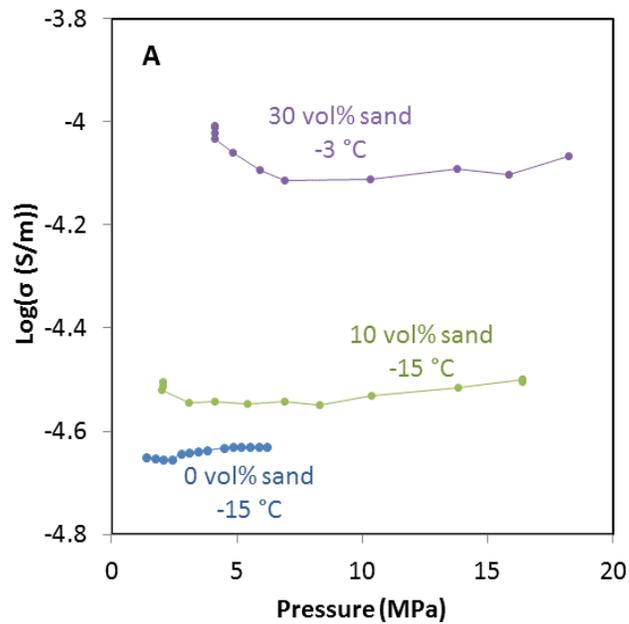

535

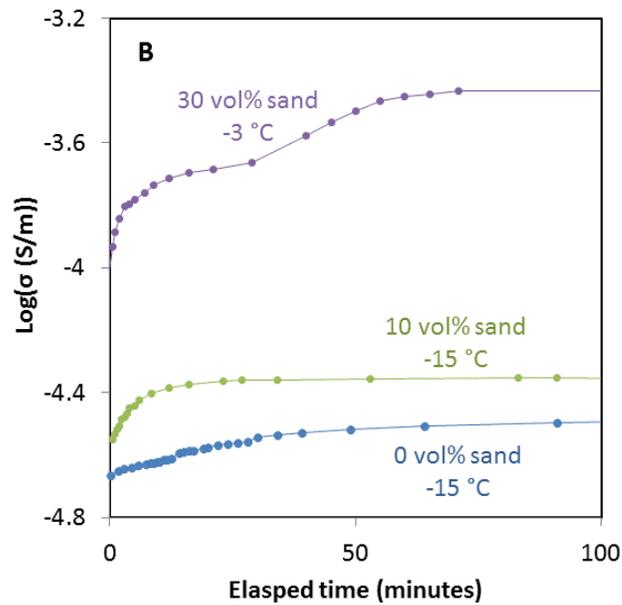

536 **Figure 4.** Electrical conductivity measurements versus inverse temperature for CH<sub>4</sub> hydrate in  
 537 mixtures with sand (closed squares, with fits shown as solid lines) or glass beads (open squares,  
 538 with fit shown as a dotted line), and ice dissociated from hydrate in mixtures with sand (filled  
 539 diamonds, with fits shown as dashed lines). Two runs were performed with ~45 vol% sand: run 4  
 540 is shown as yellow squares with 'X's; run 8 is shown as outlined, yellow squares/diamonds.

541 Linear data-fits to Equation 1 are given in Table 1 with slopes that are proportional to activation  
 542 energy ( $E_a$ ) and intercepts equal to  $\text{Log}(\sigma_0)$ .

543

544

545

546 **Figure 5.** Electrical conductivity of sample mixtures during dissociation of  $\text{CH}_4$  hydrate back  
 547 into ice as a function of pressure (A), and as a function of elapsed time (B). Samples dissociated  
 548 at a significantly higher rate at  $-3\text{ }^\circ\text{C}$  than at  $-15\text{ }^\circ\text{C}$ .

570 **Introduction**

571 This document contains sections on S1. Ionic Impurities Analyses and

572 S2. Electrical Conductivity Modeling, with supporting table and figures.

573 ***S1. Ionic Impurities Analyses***

574           The H<sub>2</sub>O from the initial seed ice and from 4 run samples (Runs 3, 5, 6, and 7) was  
575 melted and extracted to determine what ionic impurities may have been introduced to CH<sub>4</sub>  
576 hydrate grains from the sediments used in this study (OK#1 sand or glass beads). However, it is  
577 important to note that the melting process also rinses off additional materials from the sediments  
578 that were not present in the H<sub>2</sub>O while it was in the form of CH<sub>4</sub> hydrate or ice. Analyses  
579 performed on the H<sub>2</sub>O melted from mixed samples (hereafter referred to as ‘melt samples’) only  
580 indicate what ions were present at grain boundaries, not necessarily what was incorporated into  
581 the structure of CH<sub>4</sub> hydrate or ice grains. To help address this issue, we also analyzed mixtures  
582 of sand (S1-S4) and beads with water to constrain the relative amounts of impurities that may  
583 have been rinsed off into melt samples during this processing (hereafter referred to as ‘rinse  
584 samples’, as not to be confused with ‘melt samples’ obtained from actual gas hydrate synthesis  
585 runs).

586 **Methods**

587           The ice remaining after dissociation in post-run samples 3, 5, 6, and 7 was melted and  
588 analyzed to determine what impurities were present at grain boundaries. Most of the impurities  
589 measured in the water from samples were likely introduced after melting, meaning these  
590 measurements only serve to constrain what impurities might have been incorporated into the  
591 crystalline structures of gas hydrate or ice grains during experiments. The ice-sediment mixtures  
592 were loaded into 60 mL syringes. The ice was melted to water and expelled into vials through  
593 Luer lock 0.25 μm filters to separate the water from the sediment. The run 10 sample with 90  
594 vol% sand did not produce sufficient liquid for analysis. For comparison, milliQ water

595  $(5.6 \times 10^{-3} \text{ S/m})$  was mixed with varying weight ratios (0.5, 1.0, 1.5, 2.0) of glass beads or OK#1  
596 sand to determine what impurities are transferred simply by rinsing sediments. After 7 days these  
597 ‘rinse sample’ mixtures were loaded into syringes and water was expelled through Luer lock  
598  $0.25 \mu\text{m}$  filters into vials. We performed direct current electrical conductivity ( $\sigma_{\text{DC}}$ )  
599 measurements on each of these water samples using an OMEGA PHB-70x Water Analyzer with  
600 0.5% accuracy. The instrument was calibrated by 4 commercial standard solutions ranging from  
601  $10.66$  to  $2.07 \times 10^{-1} \text{ S/m}$ . Smaller volume samples were diluted with 5-12 mL MilliQ water in  
602 order to completely submerge the conductivity probe for accurate readings, and were later  
603 corrected for dilutions.

604         The water melted from run samples was analyzed to determine ionic concentrations and  
605 solution chemistry. Ionic chromatography (IC) was performed using a Metrohm 881.  
606 Concentrations of several common anions (fluoride, bromide, chloride, nitrite, nitrate, phosphate,  
607 and sulfate) and cations (ammonium, calcium, lithium, magnesium, potassium, sodium) were  
608 determined by comparing against calibration standards at several different dilutions. The reagent  
609 water used was ASTM Type II distilled, deionized water (18 Mohm) that was free of the anions  
610 of interest and particles  $> 0.20 \mu\text{m}$ . The eluent used for anions contained  $3.2 \times 10^{-3} \text{ mol/L}$  of  
611  $\text{Na}_2\text{CO}_3$  and  $1.0 \times 10^{-3} \text{ mol/L}$  of  $\text{NaHCO}_3$ . The eluent used for cations contained  $0.35 \text{ mol/L}$  of  
612  $\text{H}_2\text{C}_2\text{O}_4$ . The samples were also measured for total inorganic carbon (TIC) using an OI  
613 Analytical Aurora 1030. Prior to analyses, samples were stored in air-tight vials, and were not  
614 acidified. Analyses were performed at room temperature. The pH was calculated from IC and  
615 TIC data by assuming charge balance and using the code EQ3/6 and the data.shy database  
616 [Wolery, 1992].

## 617 **Results**

618 DC electrical conductivity measurements ( $\sigma_{DC}$ ) were performed on melt and rinse  
619 samples (Table S1, Fig. S1A). The melted seed ice that was used as starting material had a value  
620 of  $2.20(\pm 0.01) \times 10^{-3}$  S/m. The melt sample without sediment (run 3) was slightly higher in value  
621 with  $\sigma_{DC} = 1.46(\pm 0.01) \times 10^{-2}$  S/m after melting. Samples with 10 vol% (run 5) and 30 vol% (run  
622 6) of OK#1 sand had significantly higher  $\sigma_{DC}$  values of  $4.21(\pm 0.02) \times 10^{-2}$  S/m and  $2.63(\pm 0.01) \times$   
623  $10^{-1}$  S/m respectively. Run 7 contained 45 vol% glass beads (same as run 9) but failed  
624 experimentally as it left the CH<sub>4</sub> hydrate stability field during one of the temperature cycles in  
625 the synthesis step due to pressure loss. The run 7 sample was still useful for post-run analysis for  
626 impurities. This sample had the highest  $\sigma_{DC}$  of  $3.45(\pm 0.02) \times 10^{-1}$  S/m. The electrical  
627 conductivities of the melt samples were generally higher in comparison to the rinse samples  
628 when plotted as a weight ratio of sediment to water (referred to in shorthand as SiO<sub>2</sub>:H<sub>2</sub>O) (Fig.  
629 S1A). The sediment rinse samples had  $\sigma_{DC}$  that exhibited linear relationships with sediment to  
630 water weight ratios, indicating that impurities were rinsed off of sediments at amounts that were  
631 below saturation. Glass bead rinse samples had  $\sigma_{DC}$  that was 2.5 times higher than sand rinse  
632 samples.

633 IC measurements performed on the rinse and melt samples indicated that Na<sup>+</sup>  
634 concentrations had the most similar trend to the relative magnitudes of the  $\sigma_{DC}$  measurements  
635 (Figs. S1A and S2A). Glass bead rinse samples had significantly higher Na<sup>+</sup> concentrations than  
636 sand rinse samples (Fig. S2A). K<sup>+</sup>, Ca<sup>2+</sup>, and Mg<sup>2+</sup> were only detected in melt and rinse samples  
637 that contained sand (Figs. S2 B-D). The Ca<sup>2+</sup> and Mg<sup>2+</sup> quantities were similar between the melt  
638 samples and rinse samples, but melt samples contained significantly higher amounts of Na<sup>+</sup> and  
639 K<sup>+</sup> than rinse samples for a given amount of sand. Melt samples from all runs exhibited some Cl<sup>-</sup>  
640 (Fig. S2E) and smaller amounts of SO<sub>4</sub><sup>2-</sup> (Fig. S2F). The melt sample without sediment (run 3)

641 had small amounts of both Na and Cl (Table S1) that suggests  $\sim 10^{-3}$  mol/L NaCl was added  
642 during experimental handling. The total molar charge measured by IC (meq/L) was positive in  
643 all samples (Fig. S1B). Anions  $\text{CO}_3^{2-}$  and  $\text{HCO}_3^-$  were not measured by IC, so TIC measurements  
644 were performed to constrain their possible concentrations, but do not indicate their aqueous  
645 speciation (Fig. S1C). Assuming all major dissolved species that contribute to electrical solution  
646 neutrality were accounted for, and remaining charge imbalances is attributed to  $\text{H}^+$  species, we  
647 calculated pH at room temperature using EQ3/6 code (Fig. S1D). These calculations indicate that  
648 both the OK#1 sand and glass beads decrease water acidity, which is consistent with  
649 measurements performed on diluted samples that had slightly elevated pH.

## 650 Discussion

651 We attempted to constrain what impurities may have been incorporated into the  $\text{CH}_4$   
652 hydrate or ice structures from the sand or glass beads by analyzing water melted from run  
653 samples (Table S1, Fig. S1 and S2). Unfortunately, these analyses also include any other  
654 impurities that were present at grain boundaries, but were excluded from crystallization of the  
655  $\text{CH}_4$  hydrate or ice. Impurities have vastly different solubility in liquids versus solids. The effects  
656 of impurities on  $\sigma$  are also different. So caution is required in the interpretation of  $\sigma_{\text{DC}}$ , IC, and  
657 TIC measurements of water melted from samples, as they do not directly pertain to the electrical  
658 conductivities that were measured in the samples when the  $\text{H}_2\text{O}$  was  $\text{CH}_4$  hydrate or ice.

659 The electrical conductivities, and some ionic concentrations, were higher in melt samples  
660 than in rinse samples (Fig. S1 and Fig. S2). The sample with no sediment (run 3) verifies that  
661 relatively few impurities (mostly NaCl) were gained during storage, contact with the experiment  
662 apparatus, or handling of samples. Thus, the discrepancy between melt samples and the rinse  
663 samples suggests that more ionic impurities were transferred from sediments throughout

664 experimental runs than what could simply be rinsed off their surfaces. The effects of the freezing  
665 and thawing of the H<sub>2</sub>O during CH<sub>4</sub> synthesis may have allowed for more efficient chemical  
666 interaction with the surfaces of the sand and bead sediments. This could especially be the case  
667 for sand, which is likely to have somewhat weathered surfaces containing clays.

668 Contact with glass beads produced higher electrical conductivity in melt samples (run 7)  
669 than contact with sand (Fig. S1A). The  $\sigma_{DC}$  of melt samples appears to be dominated by Na<sup>+</sup>  
670 concentrations, because they show similar trends in their relative magnitudes (Fig. S1A and  
671 S2A). Na<sup>+</sup> and TIC values were very high in samples that were in contact with glass beads  
672 relative to sand. This was likely due to sodium carbonate Na<sub>2</sub>CO<sub>3</sub>, which is frequently used as  
673 flux to reduce silica melting temperature for glass making [*NIIR Board of Consultants &*  
674 *Engineers*, 2005]. The electrical conductivity of CH<sub>4</sub> hydrate-glass beads mixture (run 7) was not  
675 significantly higher than pure CH<sub>4</sub> hydrate (run 3) (Fig.4). This indicates that most impurities  
676 that were measured in higher concentrations from the surfaces of the glass beads (Na<sup>+</sup>, CO<sub>3</sub><sup>2-</sup>,  
677 and HCO<sub>3</sub><sup>-</sup>) were likely excluded during CH<sub>4</sub> hydrate formation. Conversely, at least some of the  
678 ionic impurities measured in higher concentrations from the surfaces of the sand grains (K<sup>+</sup>,  
679 Ca<sup>2+</sup>, Mg<sup>2+</sup>, NH<sub>4</sub><sup>+</sup>, Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>) were included during CH<sub>4</sub> hydrate formation to account for  
680 increased electrical conductivity values.

681 ***S2. Electrical Conductivity Modeling***

682           In this section we present our first-order attempt to model the doping effect that  
683 impurities from sand have on the electrical conductivity of mixtures with CH<sub>4</sub> hydrate.  
684 Petrophysical mixing laws can be used to describe the behavior caused by variations in the ratios  
685 of hydrate to sand and ice to sand in our sample mixtures. The sample mixtures examined in this  
686 study can be divided into 3 regimes: 1. well-connected CH<sub>4</sub> hydrate with poorly-connected sand;  
687 2. well-connected CH<sub>4</sub> hydrate with well-connected sand; 3. poorly-connected CH<sub>4</sub> hydrate with  
688 well-connected sand. This is similarly the case for ice-sand mixtures after CH<sub>4</sub> dissociation.  
689 Essentially, there are two percolation thresholds (one for each phase within sample mixtures) that  
690 must be considered. There are numerous petrophysical mixing laws [e.g., *Glover et al.*, 2000],  
691 but none adequately express mixing behaviors across percolation thresholds. This requires that  
692 each regime be modeled individually. Our limited data coverage limits us to modeling the first  
693 regime.

694 **Building the model**

695           First we assume that gas hydrate is the primary conduction path for current in our sample  
696 mixtures (see main text for supporting arguments), and that the electrical conductivity of the  
697 sand is low enough to be negligible. SEM images indicate that mixtures are generally  
698 homogenous throughout all samples. In this case a simple parallel mixing model is sufficient for  
699 describing the total electrical conductivity through well-connected phases:

$$700 \quad \sigma(\text{mixture}) = \sigma(\text{hydrate}) * \text{vol}\%(\text{hydrate}) + \sigma(\text{sand}) * \text{vol}\%(\text{sand}) \quad (\text{S1})$$

701 where  $\sigma$  is the total electrical conductivity and vol% is the volume percentage for CH<sub>4</sub> and sand  
702 respectively. The sand is not well-connected necessarily, but if  $\sigma(\text{sand}) \ll \sigma(\text{hydrate})$  then the  
703 second term would approximately be equal to zero anyway:

704 
$$\sigma(\text{mixture}) = \sigma(\text{hydrate}) * \text{vol\%}(\text{hydrate}) \quad (\text{S2})$$

705 Similar equations can be assumed for the ice after dissociation. The electrical conductivity of  
 706 pure CH<sub>4</sub> hydrate and resulting ice after dissociation was measured by *Du Frane et al.* [2011]

707 
$$\sigma(\text{pure hydrate}) = 10^{1.50}(\text{S/m})e^{-30.6(\text{kJ/mol})/RT} \quad (\text{S3})$$

708 
$$\sigma(\text{pure ice}) = 10^{5.00}(\text{S/m})e^{-45.5(\text{kJ/mol})/RT} \quad (\text{S4})$$

709 We use these measurements to constrain the model at 0 vol% sand. To model the doping effect  
 710 that impurities in sand have on gas hydrate and ice we add a second conductivity term,  
 711  $\sigma(\text{doping})$ . The concentration of impurities that can be transferred from the surfaces of the sand  
 712 grains, and thus this second conductivity term, will increase proportionally with the volume  
 713 percentage of sand

714 
$$\sigma(\text{doping}) = \sigma_0(\text{doping}) * e^{-E_a(\text{doping})/RT} * \text{vol\%}(\text{sand}) \quad (\text{S5})$$

715 The combining this with measurements on pure hydrate or ice total conductivity becomes

716 
$$\sigma(\text{hydrate}) = \sigma(\text{pure hydrate}) + \sigma(\text{doping}) \quad (\text{S6})$$

717 
$$\sigma(\text{ice}) = \sigma(\text{pure ice}) + \sigma(\text{doping}) \quad (\text{S7})$$

718 Combining these expressions gives us our fit equations for data collected on sand mixtures with  
 719 both CH<sub>4</sub> hydrate and ice

720 
$$\sigma(\text{hydrate-sand mixture}) = \{ 10^{1.50}(\text{S/m})e^{-30.6(\text{kJ/mol})/RT} +$$
  
 721 
$$\sigma_0(\text{doping}) * e^{-E_a(\text{doping})/RT} * \text{vol\%}(\text{sand}) \} * \text{vol\%}(\text{hydrate}) \quad (\text{S8})$$

722 
$$\sigma(\text{ice-sand mixture}) = \{ 10^{1.50}(\text{S/m})e^{-45.5(\text{kJ/mol})/RT} +$$
  
 723 
$$\sigma_0(\text{doping}) * e^{-E_a(\text{doping})/RT} * \text{vol\%}(\text{sand}) \} * \text{vol\%}(\text{ice}) \quad (\text{S9})$$

724 where  $\sigma_0(\text{doping})$  and  $E_a(\text{doping})$  are the only variables used to fit data. Fits were determined  
 725 using least squares regression analysis.

726 **Fitting results and discussion**

727 Only a portion of the data set could be fit to equations S8 and S9 due to changes in  
 728 connectivity of the hydrate and sand phases in mixtures as concentrations were varied. The  
 729 fitting equations are based on a simple parallel mixing law that assumes at least the conducting  
 730 phases are well connected. This works for certain concentrations of CH<sub>4</sub> hydrate/ice to sand, but  
 731 cannot be extended to concentrations where significant changes occur in connectivity of  
 732 conductive phases or mechanisms. Our data set includes sample mixtures with 0, 10, 30, ~45, 90  
 733 vol% sand. Multiple fits were attempted including data for increasing volume percentages of  
 734 sand. Only data for mixtures with < 45 vol% sand could be satisfactorily fit simultaneously to the  
 735 same solution for both ice and gas hydrate. The solutions were as follows:

$$736 \quad \sigma(\text{hydrate-sand mixture}) = \{ 10^{1.50}(\text{S/m})e^{-30.6(\text{kJ/mol})/RT} +$$

$$737 \quad \mathbf{10^{3.65}}(\text{S/m})e^{-37.6(\text{kJ/mol})/RT} * \text{vol\%}(\text{sand}) \} * \text{vol\%}(\text{hydrate}) \quad (\text{S10})$$

$$738 \quad \sigma(\text{ice-sand mixture}) = \{ 10^{1.50}(\text{S/m})e^{-45.5(\text{kJ/mol})/RT} +$$

$$739 \quad \mathbf{10^{4.95}}(\text{S/m})e^{-40.1(\text{kJ/mol})/RT} * \text{vol\%}(\text{sand}) \} * \text{vol\%}(\text{ice}) \quad (\text{S11})$$

740 These solutions are in excellent agreement with data for 0 (by definition), 10 and 30 vol% sand  
 741 for mixtures with both CH<sub>4</sub> hydrate and ice that were included in the fit, but as expected are in  
 742 poor agreement with data for ~45 or 90 vol% sand that were excluded from the fit (Fig. S3).

743 The data for ~45 vol% data has a significantly different behavior with larger increase in  
 744 electrical conductivity at lower temperatures and less overall temperature dependence. The  
 745 repeatability of this trend in a second experiment gives us high confidence in the accuracy of the  
 746 observed trends. The substantial change in overall activation energy suggests a change in  
 747 primary conduction mechanism for these mixtures. For this ratio both CH<sub>4</sub> hydrate and sand are  
 748 well connected, as evidenced by SEM images (i.e. second data regime). The electrical  
 749 conductivity data for ~90 vol% is low magnitude and has a very little temperature dependence.

750 Also SEM images of this sample mixture indicate the CH<sub>4</sub> hydrate is poorly connected and the  
751 sand is well connected (i.e. third data regime).

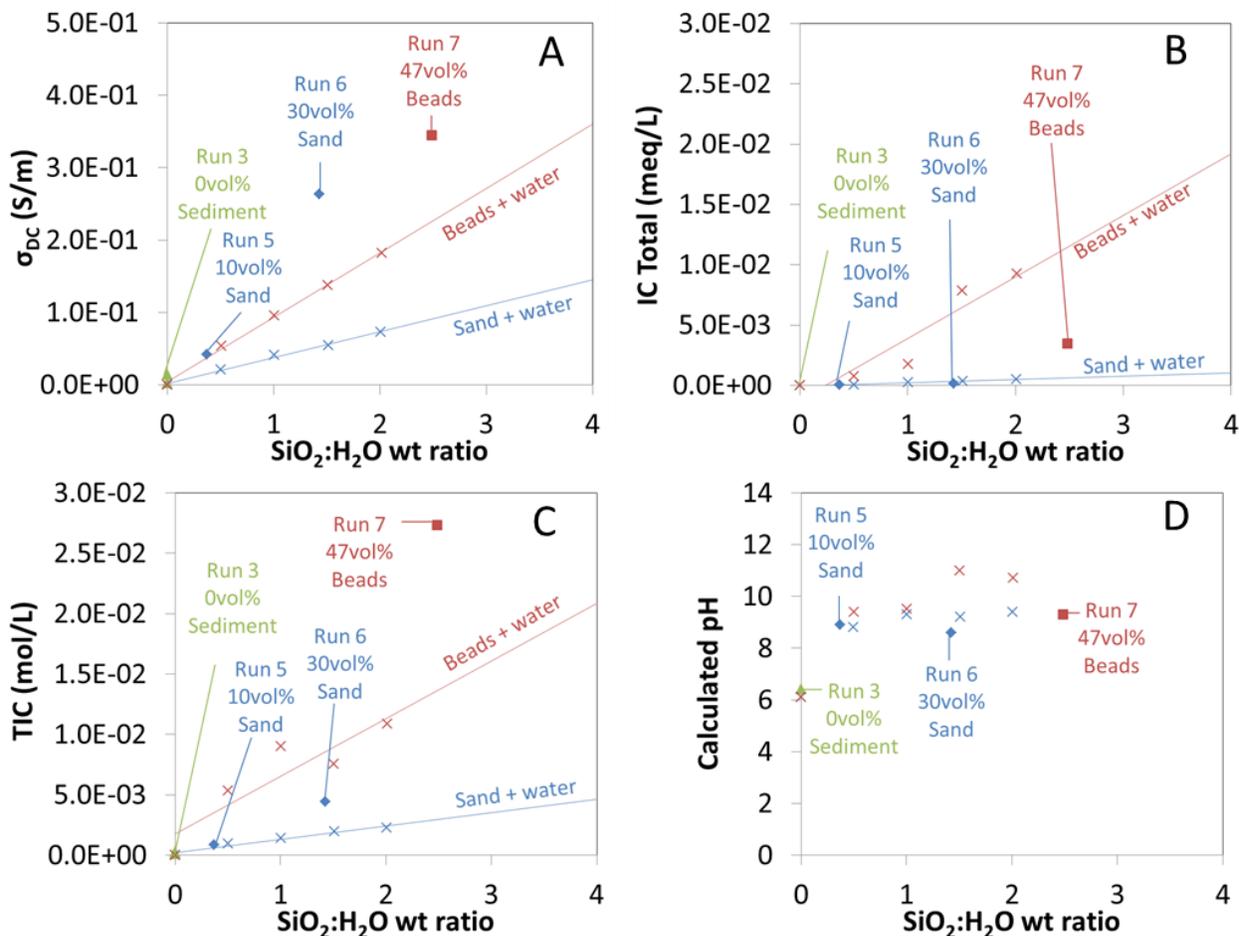

752 Electrical conductivity is highest when both sand and hydrate are connected. Although  
753 the gas hydrate still appears to be the primary conduction path throughout these mixtures, as  
754 evidenced by the very low electrical conductivity of 90 vol% sand data. This would seem to  
755 indicate that the actual interfaces between hydrate/ice and sand may be more conductive than the  
756 bulk conductivity of hydrate/ice grains, particularly at the lower temperatures in the measured  
757 range. The electrical conductivity of mixtures with 45 vol% sand may be dominated by  
758 connected interfaces between hydrate/ice and sand.

778 **Figure S3.** Electrical conductivity model of doping effect caused by impurities from sand in  
779 mixtures with A) CH<sub>4</sub> hydrate and B) ice after dissociation. Samples with 0 vol% sand are shown  
780 in blue, 10 vol% in green, 30 vol% in purple, ~45vol% in yellow, 90 vol% in red. Data fits  
781 (Equations S10 and S11) are shown as lines with the same corresponding colors. Fitting included  
782 data for mixtures with 0, 10, and 30 vol% sand, and excluded data for 45 and 90 vol% sand.
