## Abstract

22 Large-scale atmospheric forcing data can greatly impact the simulations of atmospheric  
23 process models including Large Eddy Simulations (LES), Cloud Resolving Models  
24 (CRMs) and Single-Column Models (SCMs), and impact the development of physical  
25 parameterizations in global climate models. This study describes the development of an  
26 ensemble variationally constrained objective analysis of atmospheric large-scale forcing  
27 data and its application to evaluate the cloud biases in the Community Atmospheric  
28 Model (CAM5). Sensitivities of the variational objective analysis to background data,  
29 error covariance matrix and constraint variables are described and used to quantify the  
30 uncertainties in the large-scale forcing data. Application of the ensemble forcing in the  
31 CAM5 SCM during March 2000 intensive operational period (IOP) at the Southern Great  
32 Plains (SGP) of the Atmospheric Radiation Measurement (ARM) program shows  
33 systematic biases in the model simulations that cannot be explained by the uncertainty of  
34 large-scale forcing data, which points to the deficiencies of physical parameterizations.  
35 The SCM is shown to overestimate high clouds and underestimate low clouds. These  
36 biases are found to also exist in the global simulation of CAM5 when it is compared with  
37 satellite data.

38

39 **1. Introduction**

40 Large-Eddy Simulations (LES) [e.g. *Khairoutdinov and Kogan, 2000; Zhang et*  
41 *al., 2012*], Cloud-Resolving Models (CRM)[e.g. *Khairoutdinov and Randall, 2003; Xu et*  
42 *al., 2002*], and Single-Column Models (SCM) [e.g. *Del Genio et al., 2005; Xie et al.,*  
43 *2002; Xie et al., 2005*] are important tools to develop and test physical parameterizations  
44 used in General Circulation Models (GCM) such as convections, turbulence, cloud  
45 microphysics and macrophysics. In these models, the large-scale dynamics are specified  
46 as the forcing terms to drive the physics. These forcing fields include vertical velocity  
47 and horizontal advective tendencies of temperature and moisture. To compare  
48 LES/CRM/SCM simulations with observations and to attribute model errors to  
49 deficiencies in physical parameterizations, accurate large-scale forcing data are needed.

50 Many objective analysis methods in the past have been carefully designed to  
51 derive large-scale forcing data from atmospheric sounding measurements [e.g. *Lin and*  
52 *Johnson, 1996; Ooyama, 1987*]. One widely used method is the constrained variational  
53 analysis algorithm (hereafter 1DCVA) developed by *Zhang and Lin [1997]*. Comparing  
54 to other conventional objective analysis methods, the unique feature of the 1DCVA is the  
55 use of surface and TOA observations as constraints to adjust atmospheric state variables  
56 from sounding measurements by the smallest possible amount to conserve column-  
57 integrated mass, moisture, dry static energy and momentum so that the final analysis data  
58 set is dynamically and thermodynamically consistent. This method has been used in the  
59 Atmospheric Radiation Measurement (ARM) program and several other field campaigns  
60 [*Schumacher et al., 2007; Schumacher et al., 2008; Xie et al., 2005; e.g. Xie et al., 2006;*  
61 *Xie et al., 2010a*]. Recently, *Tang and Zhang [2015]* extended the 1DCVA algorithm

62 into a three-dimensional Constrained Variational Analysis (hereafter 3DCVA) at higher  
63 horizontal resolutions and introduced additional features to improve the data quality. The  
64 new 3DCVA derives large-scale forcing data in each grid of a certain domain  
65 simultaneously, and all spatial grids are interacted with each other through advections.

66 This paper is a follow-up of *Tang and Zhang* [2015]. Because of the inevitable  
67 uncertainties in the input data and objective algorithms, and because of the large  
68 sensitivity of model results to the forcing data [*Hack and Pedretti, 2000; Hume and*  
69 *Jakob, 2005*], it is necessary to quantify and understand the uncertainties in the derived  
70 large-scale forcing data. The purpose of this paper is to introduce an ensemble approach  
71 of 3DCVA and quantify the data uncertainties by analyzing the sensitivity of the forcing  
72 data to the background data of the atmospheric state variables, the specification of the  
73 error covariance matrix, and the constrained variables, which are required by 3DCVA.

74 The ensemble forcing data enable us to more confidently attribute errors in the  
75 LES/CRM/SCM to physical sources when their simulated results are compared with  
76 observations. We will show the applications of using the ensemble forcing data to  
77 evaluate the simulated clouds in the Community Atmospheric Model (CAM5). Clouds  
78 represent one of the largest uncertainties in current GCM simulations. Cloud simulations  
79 are found to have large discrepancies from satellite- and ground- based observations.  
80 *Zhang et al.* [2005] found that the majority of ten GCMs only simulated 30% to 40% of  
81 the observed middle clouds and half of them underestimate low clouds comparing to  
82 satellite cloud analysis from ISCCP (International Satellite Cloud Climatology Project)  
83 and CERES (Cloud and the Earth's Radiant Energy System). *Xie et al.* [2005] evaluated  
84 9 SCMs and 4 CRMs using ARM Baseline Microphysical Retrieval (MICROBASE)

85 ground measurements for a mid-latitude cyclone system, and found that the models  
86 generally captured the bulk characteristics of frontal clouds but differed significantly in  
87 the detailed structures. *Klein et al.* [2009] compared the simulations from 17 SCMs and  
88 9 CRMs for an Arctic mixed phase cloud case. They found that the median simulated  
89 liquid water path (LWP) is about one-third of the observed value, and the spread among  
90 models are quite significant due to different physical schemes. *Jiang et al.* [2012]  
91 examined 19 CMIP5 (Coupled Model Intercomparison Project phase 5) models and  
92 found that both model-observation difference and model spread are large especially at the  
93 upper troposphere levels. Although the model discrepancies are mainly attributed to  
94 cloud parameterization errors other than to large-scale errors [e.g. *Su et al.*, 2013], it is  
95 unclear how the physical parameterization and the large-scale atmospheric circulation  
96 each contribute to the model errors. Moreover, the uncertainties of cloud retrievals from  
97 different measurements and different retrieval algorithms are also large enough to affect  
98 the evaluation of model results [*Huang et al.*, 2012; *Zhao et al.*, 2012]. With the  
99 uncertainty of large-scale dynamics and observations specified, we can better attribute the  
100 source of model biases.

101         The rest of the paper is organized as follows: Section 2 describes the method of  
102 ensemble 3DCVA and data used in the method. Section 3 shows the ensemble mean  
103 features of large-scale forcing data for one selected case and the sensitivities due to  
104 different background data, error covariance matrix and constraint variables. Section 4  
105 shows the sensitivities of SCM simulations due to large-scale forcing data and provides  
106 an example of cloud bias evaluation and error source diagnosis. Summary and discussion  
107 are given in Section 5.

108

## 109 2. Method, Data and Model

110 As described in *Tang and Zhang* [2015], the 3DCVA follows the general idea of  
111 1DCVA [*Zhang and Lin*, 1997] that the atmospheric state variables (refers as background  
112 data hereafter)  $u$ ,  $v$ ,  $q$  and  $s$  are adjusted by minimizing the following cost function:

$$113 I = (u - u_o)^T B_u^{-1} (u - u_o) + (v - v_o)^T B_v^{-1} (v - v_o) + (q - q_o)^T B_q^{-1} (q - q_o) + (s - s_o)^T B_s^{-1} (s - s_o) \\ 114 \quad (1)$$

115 and satisfying the column-integrated conservation of mass, moisture and energy  
116 simultaneously across all spatial grids in the model domain:

$$117 \quad \langle \nabla \cdot \vec{V} \rangle = -\frac{1}{g} \frac{dP_s}{dt} \quad (2)$$

$$118 \quad \frac{\partial \langle q \rangle}{\partial t} + \langle \nabla \cdot \vec{V} q \rangle = E_s - P_{rec} - \frac{\partial \langle q_l \rangle}{\partial t} \quad (3)$$

$$119 \quad \frac{\partial \langle s \rangle}{\partial t} + \langle \nabla \cdot \vec{V} s \rangle = R_{TOA} - R_{SRF} + L_v P_{rec} + SH + L_v \frac{\partial \langle q_l \rangle}{\partial t} \quad (4)$$

120 In addition, it adds the extra radiative constraints:

$$121 \quad \frac{\partial s}{\partial t} + \nabla \cdot (\vec{V} s) + \frac{\partial \omega s}{\partial p} = Q_{rad} \quad (5)$$

122 at each level above observed cloud top (or a specified level when observed cloud top is  
123 low or absent) to physically reduce the spurious heating and cooling centers that are often  
124 seen near tropopause in both conventional objective analysis methods and 3DCVA. In  
125 the cost function Eq. (1),  $u$ ,  $v$ ,  $q$ ,  $s$  are column vectors of horizontal winds, water vapor

126 mixing ratio and dry static energy ( $s = C_p T + gz$ , where  $C_p$  is heat capacity of air at  
127 constant pressure) for all grids in each time step. The superscript  $T$  denotes the transpose  
128 of a vector, the subscript  $o$  denotes the initial state, and  $B$  represents error covariance  
129 matrix for each state variable. In the constraint equations (2)-(5), the bracket represents  
130 vertical integration from the surface to the top of atmosphere (TOA),  $E_s$  is surface  
131 evaporation,  $P_{rec}$  is surface precipitation,  $L_v$  is the latent heat of vaporization,  $q_l$  is cloud  
132 liquid water content,  $R_{TOA}$  and  $R_{SRF}$  are net downward radiation at TOA and at surface,  
133  $SH$  is surface sensible heat flux,  $\omega$  is vertical velocity in pressure coordinate, and  $Q_{rad}$  is  
134 radiative heating rate calculated by the Rapid Radiative Transfer Model for GCMs.  
135 Other variables are as commonly used in meteorology.

136 The details of 3DCVA are described in *Tang and Zhang* [2015]. Here we  
137 highlight three sources of uncertainties (refers as elements hereafter) that impact the  
138 accuracy of 3DCVA results: background data, error covariance matrix and constraint  
139 variables. Background data are the first guess of the 3DCVA; all the adjustments are  
140 based on the original background data. Error covariance matrix, which is represented by  
141  $B$  in Eq. (1), determines how the background data are adjusted spatially. Constraint  
142 variables, which are the right-hand-side terms of the constraint equations Eq. (2)-(5),  
143 control the budget of the whole system. Previous studies [*Xie et al.*, 2004; *Zhang et al.*,  
144 2001] have shown that precipitation is the dominant constraint variables during rainy  
145 periods. In this study, we run 3DCVA using different combinations from six background  
146 data, five error covariance matrices and three precipitation estimates (Table 1, details  
147 described below) to analyze the uncertainties in the derived forcing fields.

<b>Background data</b>	RUC, ERA-interim, CFSR, JRA55, MERRA, NARR (details see Table 2)
<b>Error covariance matrix</b>	Calculated from variance of time series, only auto correlation.
	Calculated from variance of ensemble members, only auto correlation.
	Calculated from variance of ensemble members, vertical correlation.
	Calculated from variance of ensemble members, horizontal correlation.
	Calculated from variance of ensemble members, horizontal and vertical correlation.
<b>Constraint variables</b>	Arkansas-Red Basin River Forecast Center (ABRFC) gridded precipitation products
	Upper bound: $1.4 \times$ ABRFC precip amount
	Lower bound: $0.6 \times$ ABRFC precip amount

148 Table 1: different background data, error covariance matrix and constraint variables used in  
149 ensemble 3DCVA.

150

<b>Name</b>	<b>Data Assimilation</b>	<b>Assimilation Intervals</b>	<b>Model Resolution</b>	<b>Model Vertical levels</b>
<b>ERA-interim</b> <i>Dee et al., 2011</i>	4DVAR	12 hour	T255 (79km×79km)	60
<b>CFSR</b> <i>Saha et al., 2010</i>	3DVAR with flow dependence error variance	6 hour	T382 (38km×38km)	64
<b>MERRA</b> <i>Rienecker et al., 2011</i>	3DVAR with incremental analysis update (IAU)	6 hour	$1/2^\circ \times 2/3^\circ$	72
<b>JRA55</b> <i>Kobayashi et al., 2015</i>	4DVAR	6 hour	TL319 (55km×55km)	60
<b>NARR</b> <i>Mesinger et al., 2006</i>	3DVAR with precipitation assimilated	3 hour	32km×32km	45
<b>RUC</b> <i>Benjamin et al., 2004</i>	3DVAR	1 hour	40km×40km	40

151 Table 2: the six background data used in the ensemble 3DCVA. All datasets are interpolated into  
152  $0.5^\circ \times 0.5^\circ$  horizontal resolution, 27 vertical levels from 1000hPa to 100hPa and 3-hourly time  
153 resolution.

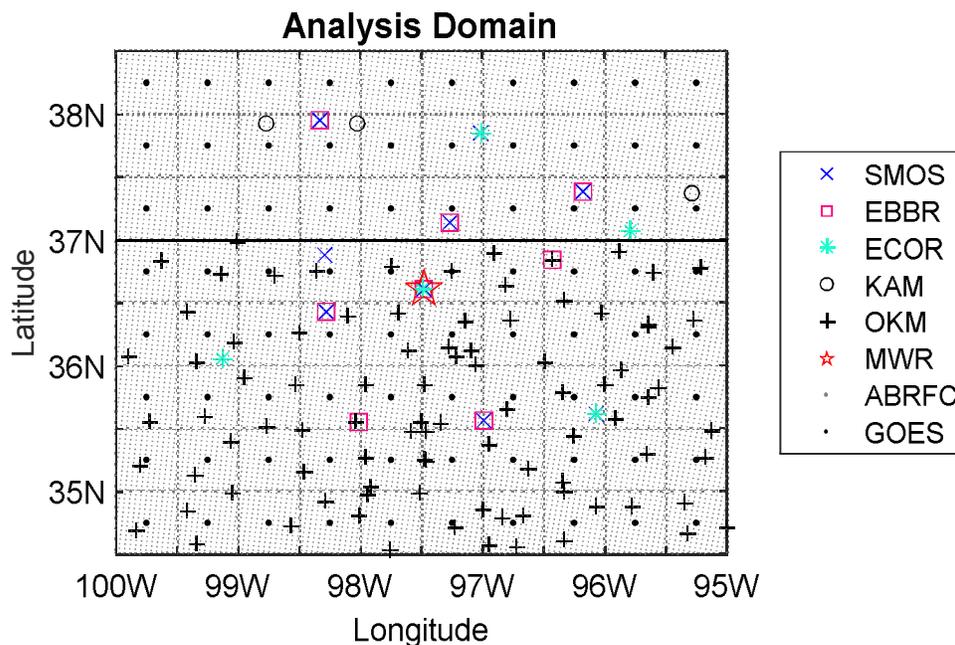

154

155           The six background data are obtained from reanalysis/analysis products listed in  
156 Table 2. They are linearly interpolated into  $0.5^\circ \times 0.5^\circ$  horizontal resolution, 3-hourly  
157 time resolution and 27 vertical levels from 1000 hPa to 100 hPa. Most of the constraint  
158 variables are derived from ARM surface station measurements, which include the  
159 following datasets:

- 160       • Surface Meteorological Observation Stations (SMOS) measuring precipitation,  
161           pressure, winds, temperature, and relative humidity at the surface.
- 162       • Energy Budget Bowen Ratio (EBBR) stations measuring surface latent and  
163           sensible heat fluxes and surface broadband net radiative flux.
- 164       • Eddy Correlation Flux Measurement System (ECOR) providing in situ half-hour  
165           averages of the surface vertical fluxes of momentum, sensible heat flux, and latent  
166           heat flux.
- 167       • Oklahoma and Kansas mesonet stations (OKM and KAM) measuring surface  
168           precipitation, pressure, winds, and temperature.
- 169       • Microwave Radiometer (MWR) stations measuring the column precipitable water  
170           and total cloud liquid water.

171           These surface measurements are interpolated into  $0.5^\circ \times 0.5^\circ$  horizontal resolution  
172 covering the SGP domain. If there are actual measurements within the  $0.5^\circ \times 0.5^\circ$  grid  
173 box, simple arithmetic averaging is used to obtain the value for that grid box. Under  
174 circumstances that multiple instruments observe the same quantities, their measurements  
175 are merged in the arithmetic averaging process with a weighting function depending on  
176 their quality. If there is no actual measurement in the grid box, the Barnes scheme  
177 [*Barnes*, 1964] is used with the length scale of  $L_x=50\text{km}$ ,  $L_y=50\text{km}$ , and  $L_t=6\text{hr}$  to fill the

178 missing grid box. The satellite measurements of radiative fluxes and cloud top pressure  
 179 are available at NASA Langley [Minnis *et al.*, 2008] measured by the Geostationary  
 180 Operational Environment Satellite 8 (GOES8) in  $0.5^\circ \times 0.5^\circ$  grid box. The precipitation  
 181 rate data is obtained from the 4-km resolution gridded precipitation products from  
 182 Arkansas-Red Basin River Forecast Center (ABRFC) based on WSD-88 rain radar and  
 183 gauge measurements, and is averaged into  $0.5^\circ \times 0.5^\circ$  horizontal resolution and 3-hourly  
 184 time resolution. The spatial distribution of the surface and TOA measurements used in  
 185 this study are shown in Figure 1.

186  
 187 Figure 1: Analyzed SGP domain and surface/TOA observations. Different marks show different  
 188 instruments. Gray lines show  $0.5^\circ \times 0.5^\circ$  grids in 3DCVA which are the same as grids of GOES  
 189 satellite products (black dots). Black line at 37°N indicates the boundary between Oklahoma  
 190 (below) and Kansas (above).

191

192 Surface and TOA measurements of constraint variables contain errors from  
 193 instrument uncertainties, assumptions and limitations in the retrieval algorithms, and

194 interpolation from stations to regular grids. As shown in *Xie et al.* [2004], precipitation is  
195 the most dominant constraint during precipitation periods. In this study, we will focus on  
196 the impact of precipitation uncertainties on the derived large-scale forcing data.  
197 Following *Xie et al.* [2014], we consider a 40% fractional root-mean-square error (RMSE)  
198 for ABRFC rainfall products, and use the estimated rain rate, the upper bound (1.4 times  
199 estimated rain rate), and the lower bound (0.6 times estimated rain rate) of the uncertainty  
200 to form the ensemble members. The 40% uncertainty is only considered on the  
201 magnitude of the rain rate.

202 We have two methods to calculate the error covariance matrix. One method is the  
203 original algorithm [*Zhang and Lin*, 1997; *Zhang et al.*, 2001] in 1DCVA, which  
204 calculates the covariance from the variance of time series of the background data plus  
205 instrument and measurement uncertainties with no correlation. The other method is  
206 described in *Tang and Zhang* [2015] which calculates the covariance by using the  
207 anomaly of different background data relative to their ensemble mean. In this method,  
208 we can have the different correlation types of no correlation, vertical correlation only,  
209 horizontal correlation only, and both horizontal and vertical correlations in which  
210 adjustments of each grid point will have different correlations to its surrounding grids and  
211 levels. In total we can have five error covariance matrices to run the ensemble 3DCVA.  
212 Combining 6 background fields, 3 precipitation rates (representing constraint variables),  
213 and 5 covariance matrices, we therefore have a total of 90 3DCVA ensemble members.

214 A SCM version of CAM5 (SCAM5) is used to test the impact of uncertainties in  
215 the large-scale forcing data. CAM5 is the latest version of the NSF/DOE Community  
216 Atmospheric Model developed at the Nation Center for Atmospheric Research (NCAR),

217 which contains a range of significant enhancements in the representation of moist  
218 physical processes relative to its predecessors [Neale *et al.*, 2012]. These include: (1) a  
219 turbulent kinetic energy (TKE) based boundary layer scheme that can explicitly simulate  
220 stratus-radiation-boundary layer interactions [Bretherton and Park, 2009]; (2) a new  
221 shallow convection scheme combined with the above boundary layer scheme [Park and  
222 Bretherton, 2009]; and (3) a new bulk two-moment cloud microphysics scheme for  
223 stratiform-clouds [Morrison and Gettelman, 2008] that predicts both mixing ratios and  
224 number concentrations of cloud droplets (liquid) and crystals (ice). CAM5 is part of the  
225 Community Earth System Model (CESM) that has been used in Phase 5 of the Coupled  
226 Model Intercomparison Project (CMIP5).

227         The observed cloud properties used to evaluate the SCAM5 simulations are  
228 obtained from ARM Baseline Microphysical Retrieval (MICROBASE) which is a cloud  
229 retrieval product combining multiple measurements from cloud radar, lidar, ceilometer,  
230 microwave radiometer and soundings. Other variables such as liquid water path (LWP)  
231 and radiative fluxes are obtained from ARM Best Estimate (ARMBE) products [Xie *et al.*,  
232 2010b] at SGP central facility. We average these data into 3-hour intervals in order to  
233 compare with SCAM5 simulations.

234         The satellite retrievals used to evaluate the CAM5 GCM results is the merged  
235 CALIPSO, CloudSat, CERES, and MODIS product C3M [Kato *et al.*, 2011]. It has  
236 global coverage from July 2006 to June 2010 for 4 years. Cloud fraction in this product  
237 is obtained from CALIPSO data with CloudSat clouds assigned into CALIPSO bins.  
238 Liquid water content (LWC) and ice water content (IWC) are derived from the radar-only  
239 algorithm from CloudSat and normalized by LWP from MODIS measurements.

240

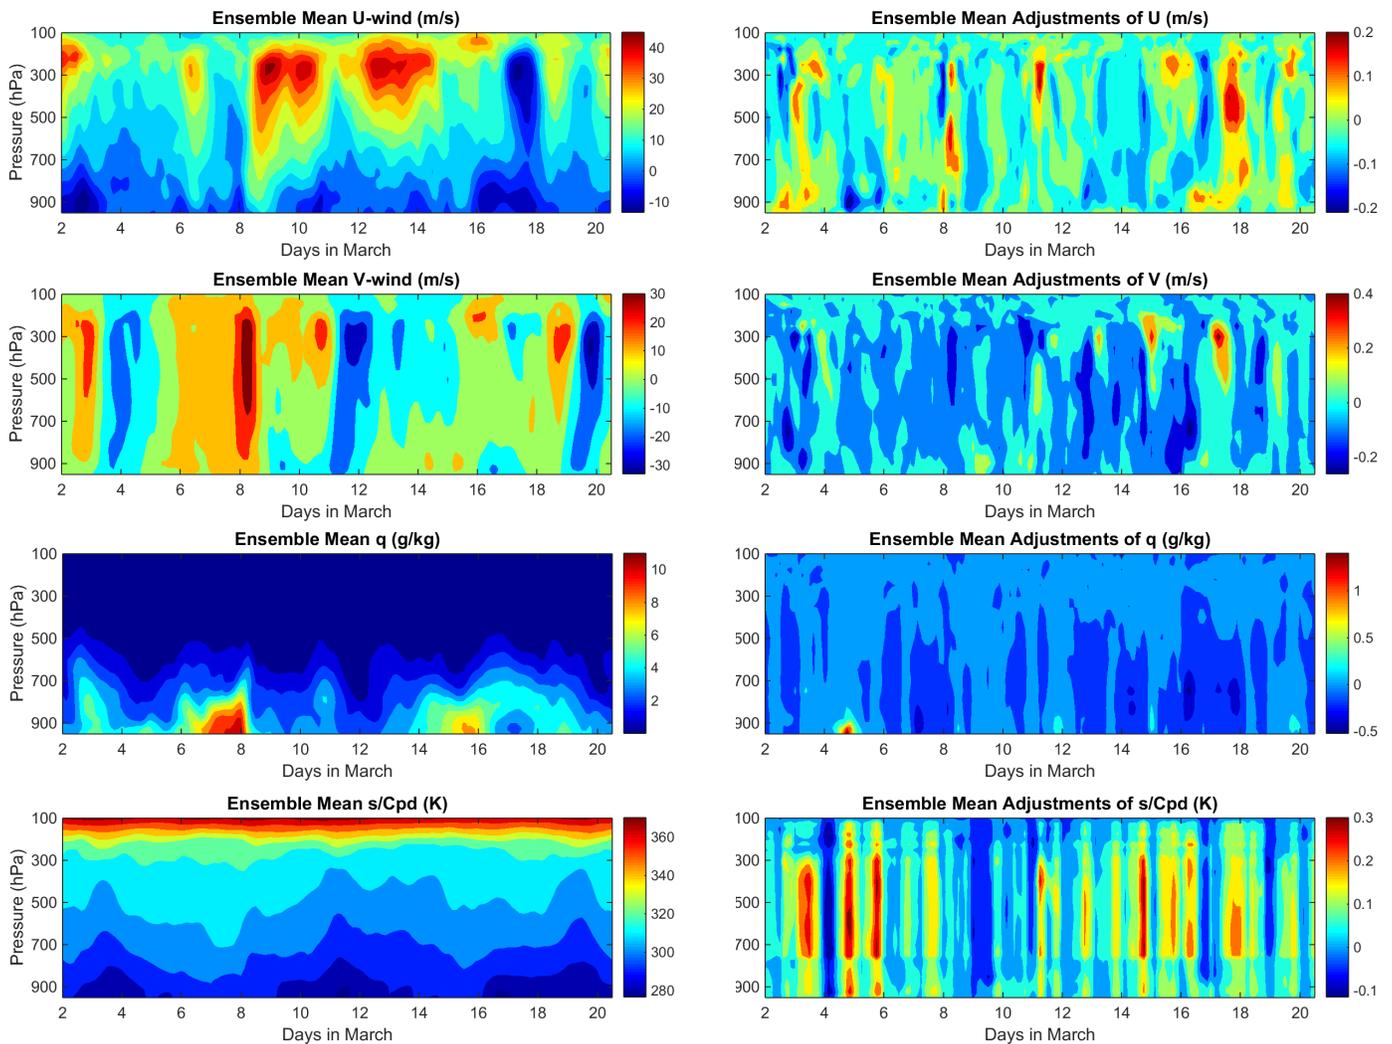

### 241 3. Ensemble Constrained Variational Analysis of Large-Scale Forcing Data

#### 242 3.1 Ensemble mean

243 The ARM March 2000 Intensive Operational Period (IOP) at the Southern Great  
244 Plains (SGP) is used in this study. This IOP contains several precipitation events with  
245 various types of clouds, which has been extensively examined in earlier process studies  
246 [e.g. *Xie et al.*, 2005; *Xu et al.*, 2005]. The 3D structure of a mid-latitude cyclone case on  
247 3 March has been analyzed by *Tang and Zhang* [2015]. Here we emphasize the SGP  
248 domain averaged large-scale forcing data during the whole IOP. The SGP domain in this  
249 study is following the domain used in *Tang and Zhang* [2015], which is a rectangle  
250 domain from 34.5-39°N, 95-100°W, with 0.5°×0.5° horizontal resolution shown in  
251 Figure 1.

252 Figure 2 shows the domain averaged ensemble mean analyzed  $u$ ,  $v$ ,  $q$ ,  $s$  from the  
253 ensemble 3DCVA, and the domain averaged ensemble mean adjustments for each  
254 variable. The domain mean adjustments of horizontal winds are smaller than 0.5 m s<sup>-1</sup>,  
255 but the standard deviation of adjustments on horizontal grids (not shown) are in the  
256 magnitude of 1 m s<sup>-1</sup>, indicating that the winds adjustments have compensatory effects  
257 horizontally, which brings large change to the divergence and advections. The average  
258 adjustment of  $q$  is generally smaller than 0.5 g kg<sup>-1</sup>, except for one low-level point at 18Z  
259 on 4 March. Adjustments of  $s$  have a diurnal cycle with warm adjustments of ~0.3K in  
260 the daytime and cold adjustments of ~0.1K in the nighttime. The periodic feature of  $s$   
261 adjustments indicates the inconsistency of diurnal cycle in the background data and in the

262 column energy budget, which may due to the unrealistic simulations of diurnal cycle in  
 263 reanalysis/analysis models. The domain averaged adjustment of  $q$  and  $s$  has a similar  
 264 magnitude to the standard deviation of adjustments on horizontal grids (not shown).

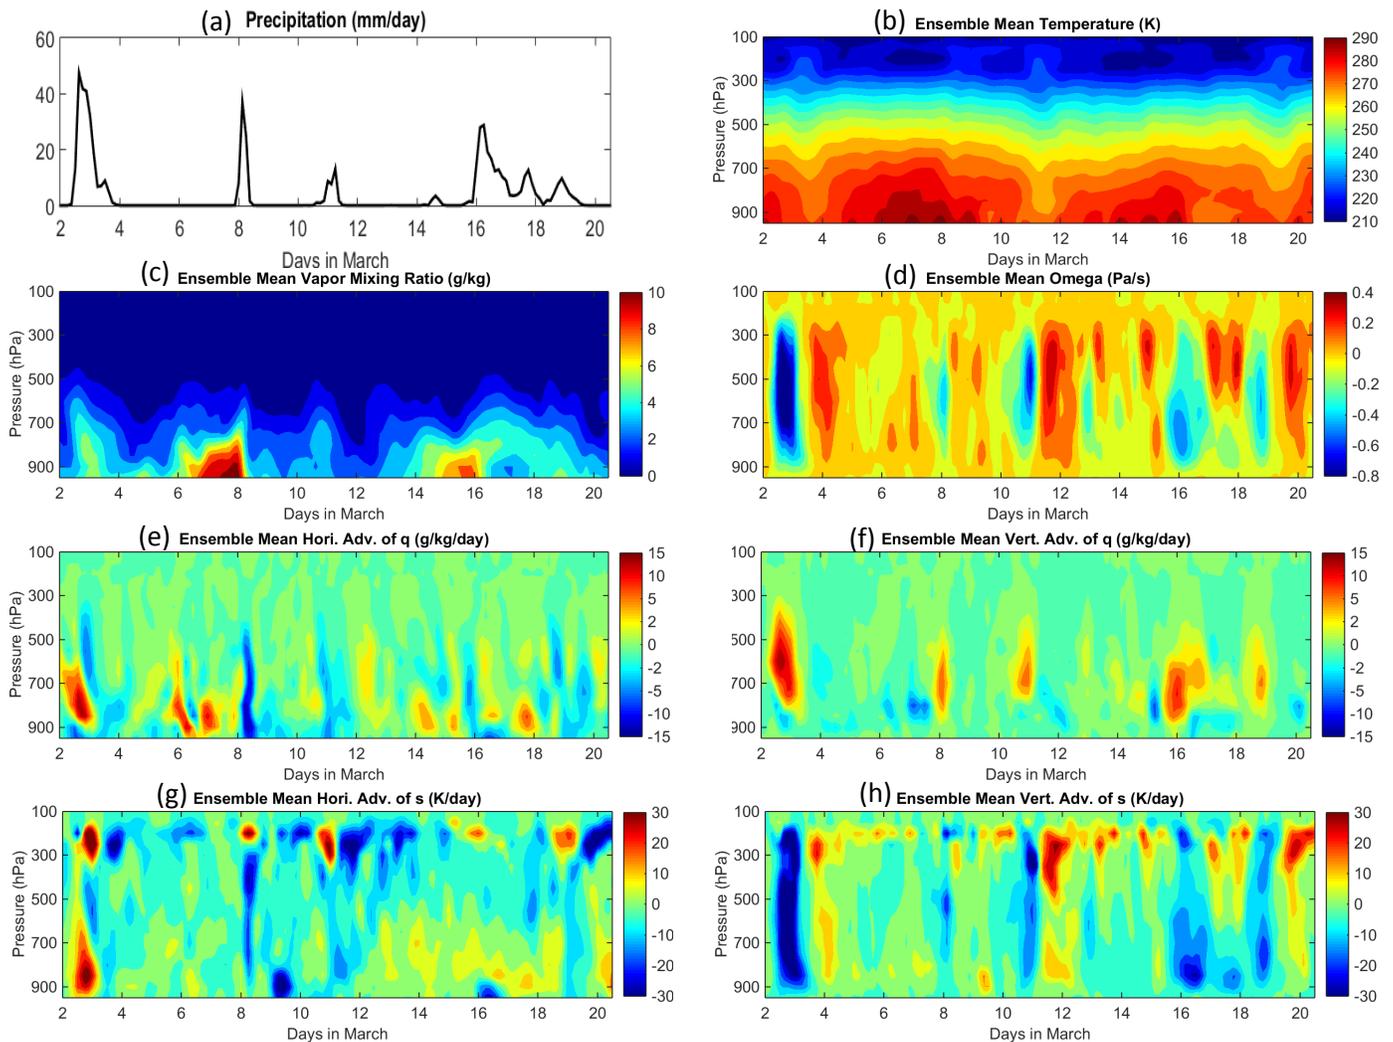

265

266 Figure 2: (left) SGP domain averaged ensemble mean horizontal winds, moisture and dry static  
 267 energy ( $u$ ,  $v$ ,  $q$ ,  $s$ ) and (right) SGP domain averaged adjustments of  $u$ ,  $v$ ,  $q$ ,  $s$ .

268

269            Figure 3 shows the domain averaged precipitation and ensemble mean  
 270 temperature, moisture, vertical velocity ( $\omega$ ), as well as horizontal and vertical  
 271 advections of  $q$  and  $s$ , which are key variables of the large-scale forcing data. The  
 272 precipitation occurs on 2-3 March, 8 March, 11 March, and 16-19 March, separately. The  
 273 rising motion and advections of  $q$  and  $s$  correspond well with these events. The general  
 274 patterns are also consistent with forcing data derived from 1DCVA (not shown), which  
 275 uses the same source of constraint variables within a slightly smaller domain at SGP. In  
 276 the next section, we will discuss the impact of the three elements of ensemble 3DCVA on  
 277 the analyzed large-scale forcing data.

278

279 Figure 3: (a) SGP domain averaged precipitation and domain averaged ensemble mean profiles of  
280 (b) temperature, (c) water vapor mixing ratio, (d) vertical velocity, (e – h) horizontal and vertical  
281 advectations of  $q$  and  $s$ .

282

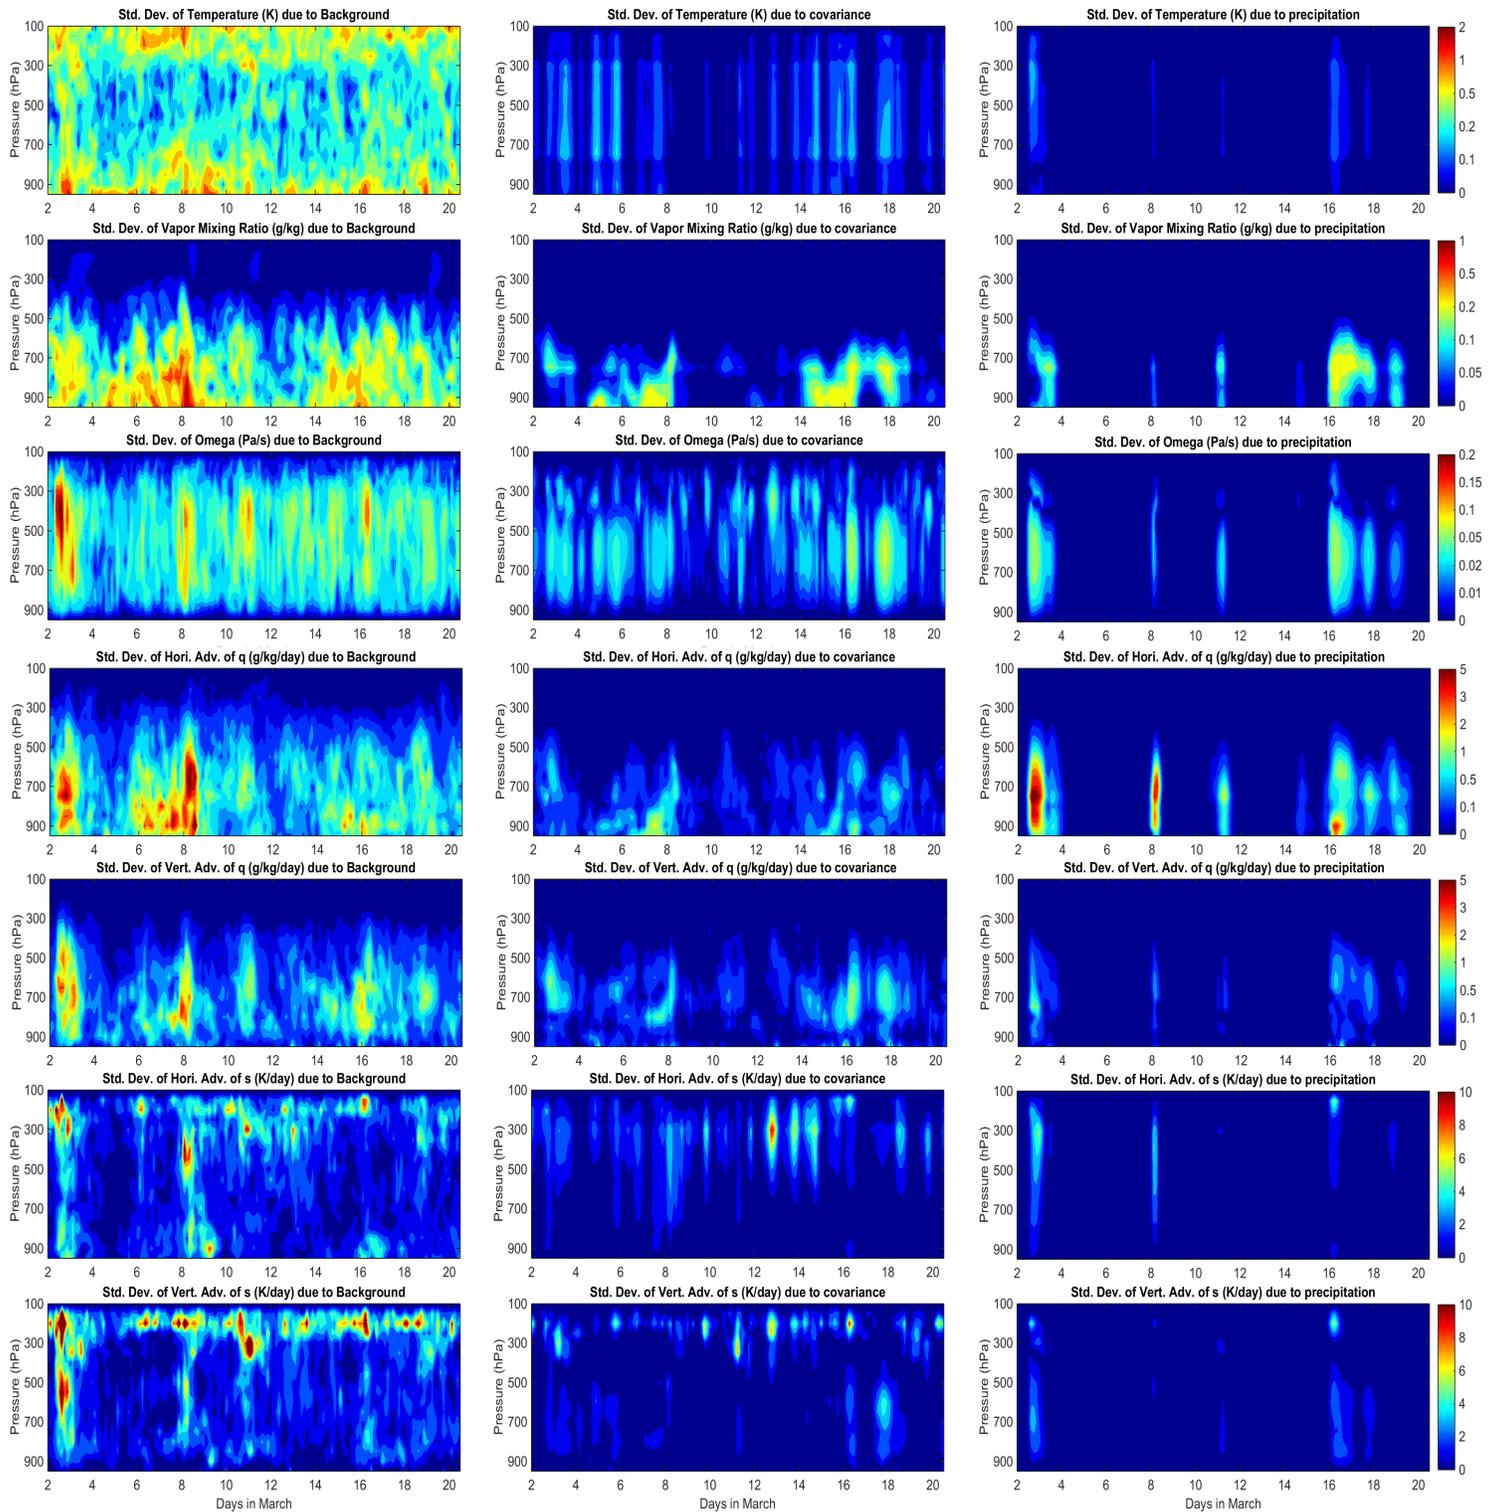

### 283 3.2 Analysis of sensitivity and uncertainty

284 To understand the sensitivities of large-scale forcing data to different elements in  
285 3DCVA, we calculated the standard deviations of large-scale forcing data due to different  
286 background data, error covariance matrices and precipitation rates (Figure 4). For each  
287 one element (such as background data), we average the large-scale forcing data over the  
288 other two elements (such as error covariance matrix and precipitation rate). The  
289 magnitude of standard deviation of temperature and water vapor mixing ratio is generally  
290 smaller than 2K and  $1\text{g kg}^{-1}$ , respectively; the magnitude of vertical velocity and  
291 advective tendencies of  $q$  and  $s$  are around  $0.2\text{Pa s}^{-1}$ ,  $5\text{g kg}^{-1}\text{ day}^{-1}$ , and  $10\text{K day}^{-1}$ ,  
292 respectively. The relative uncertainties of vertical velocity and advective tendencies are  
293 much larger than the relative uncertainties of temperature and moisture. The standard  
294 deviation due to different background data is larger than that due to error covariance and  
295 precipitation in most of time, indicating the importance of the initial first guess to the  
296 final forcing data. For uncertainties due to precipitation, horizontal moisture advection  
297 has much larger uncertainty than other variables, which indicates tight relationship  
298 between the horizontal moisture advection and precipitation process.

299

300

301

302

303 Figure 4: the standard deviations of large-scale forcing data (from top to bottom: T, q,  $\omega$ ,  
 304 horizontal and vertical advections of q and s) to different background data (left), error covariance  
 305 matrices (middle) and precipitation rates (right).

306 To investigate the overall uncertainties of large-scale forcing data due to all the  
307 three elements, we define the relative 1-sigma uncertainty as the standard deviation of the  
308 90 ensemble members divided by the temporal standard deviation of the ensemble mean  
309 fields. As shown in Table 3, during the whole IOP, the domain mean 1-sigma uncertainty  
310 is about 1.5% for temperature and 5.6% for vapor mixing ratio. If we separate it into  
311 precipitation periods and non-precipitation periods, the 1-sigma uncertainty in  
312 temperature (water vapor mixing ratio) is 1.6% (6.3%) for precipitation periods and 1.4%  
313 (4.9%) for non-precipitation periods. For the analyzed forcing fields, the mean 1-sigma  
314 uncertainty in vertical velocity and advective tendencies of  $q$  and  $s$  is 21.6%, 24.9% and  
315 27.0% for the whole IOP, 26.7%, 32.5% and 31.9% for precipitation periods, and 16.7%,  
316 17.6% and 22.4% for non-precipitation periods, respectively. It is clear that these large-  
317 scale forcing data are more uncertain during precipitation periods than during non-  
318 precipitation period.

319

	<b>Temperature</b>	<b>Water Vapor Mixing Ratio</b>	<b>Vertical Velocity</b>	<b>Advections of <math>q</math></b>	<b>Advections of <math>s</math></b>
Whole IOP	1.5%	5.6%	21.6%	24.9%	27.0%
Precip	1.6%	6.3%	26.7%	32.5%	31.9%
Non- precip	1.4%	4.9%	16.7%	17.6%	22.4%

320

321 Table 3: The 1-sigma uncertainties of large-scale forcing data due to all different elements. For  
322 advections of  $q$  and advections of  $s$ , the uncertainty is the average of the uncertainties of  
323 horizontal and vertical advections.

324           The vertical profiles of these large-scale forcing data averaged over the  
325 precipitation period and non-precipitation period and their standard deviations are shown  
326 in Figure 5. There are significant differences between vertical profiles of the  
327 precipitation period and non-precipitation period. During the precipitation period, it has  
328 lower temperature and higher moisture at lower level. The vertical velocity shows rising  
329 motion throughout the whole troposphere during the precipitation period while sinking  
330 motion during the non-precipitation period, which contributes to opposite signs in vertical  
331 advections of  $q$  and  $s$ . Advections of  $s$  at upper-levels have larger sensitivities than at  
332 mid- and low-levels, which may be related to the relatively larger gradient of  $s$  at the  
333 tropopause.

334

335

336 Figure 5: Ensemble mean vertical profiles of (up): temperature, vapor mixing ratio, vertical  
 337 velocity, (middle): horizontal and vertical advection of  $q$  and (bottom): horizontal and vertical  
 338 advection of  $s$  averaged for precipitation period (blue) and non-precipitation period (red). The  
 339 time-mean standard deviations are shown in shade.

340

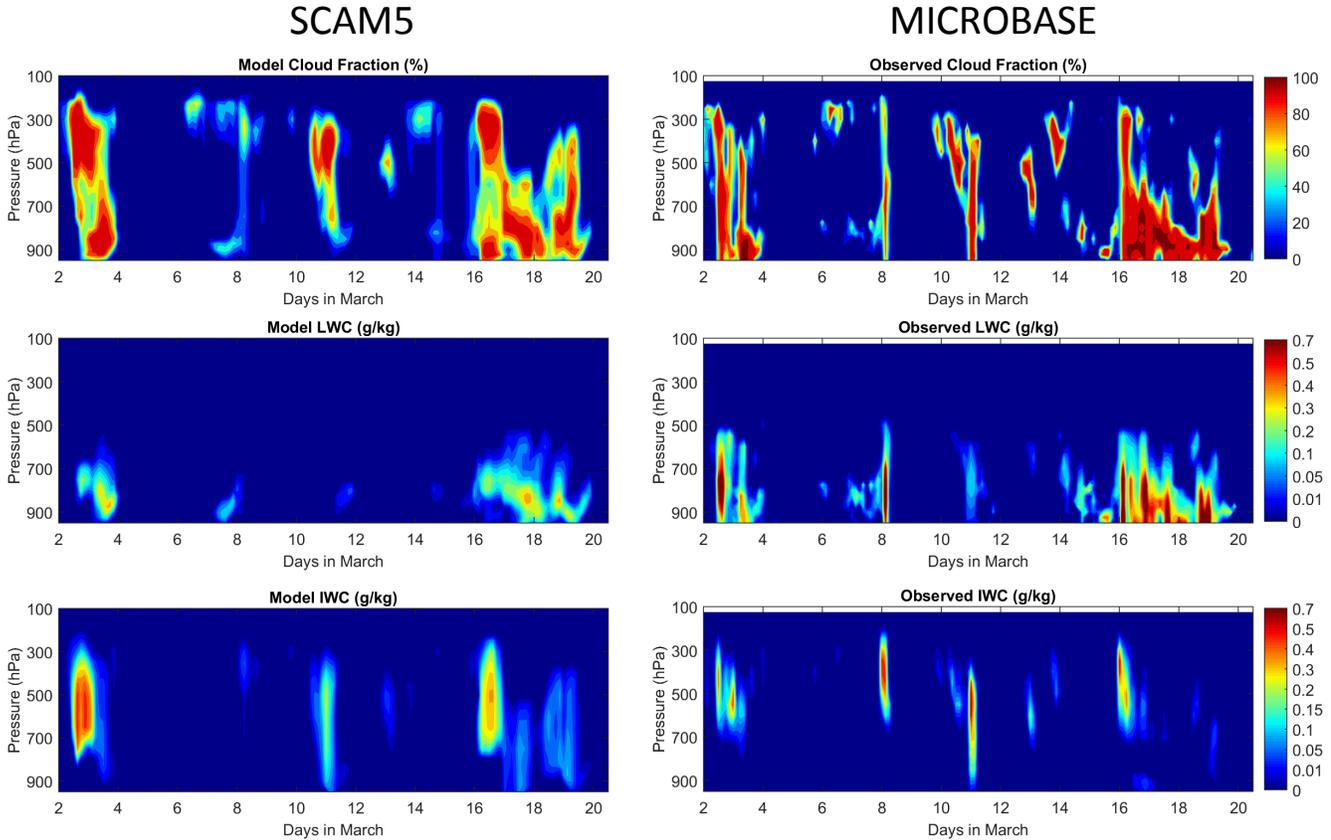

## 341 **4. Application of Ensemble Forcing Data on Evaluating Cloud Bias in CAM5**

### 342 4.1 Sensitivity of SCM simulations

343 We next analyze the sensitivity of SCM simulations to different elements in the  
344 large-scale forcing data. Here we run SCAM5 using each member of the ensemble large-  
345 scale forcing data (SGP domain mean), restarting at 15Z every day from 1 March to 19  
346 March for 36 hours without relaxation, and choose the hour 9 to 33 of the simulations  
347 (00Z to 24Z of the next day) to test the sensitivities of model results to different  
348 background data, error covariance matrices and constraint variables. Surface sensible  
349 and latent heat fluxes are prescribed from the forcing data.

350 The time-pressure cross sections of the ensemble mean simulated cloud fraction,  
351 liquid water content (LWC) and ice water content (IWC) are shown in Figure 6 (left).  
352 Also shown in the figure are the observations obtained from MICROBASE during this  
353 period (right). Note that the model IWC in this study includes both cloud ice and snow  
354 since observation does not separate the two. The models captured most of the major  
355 cloud events during the IOP, with good consistency to observations especially in the  
356 cloud fraction.

357

358

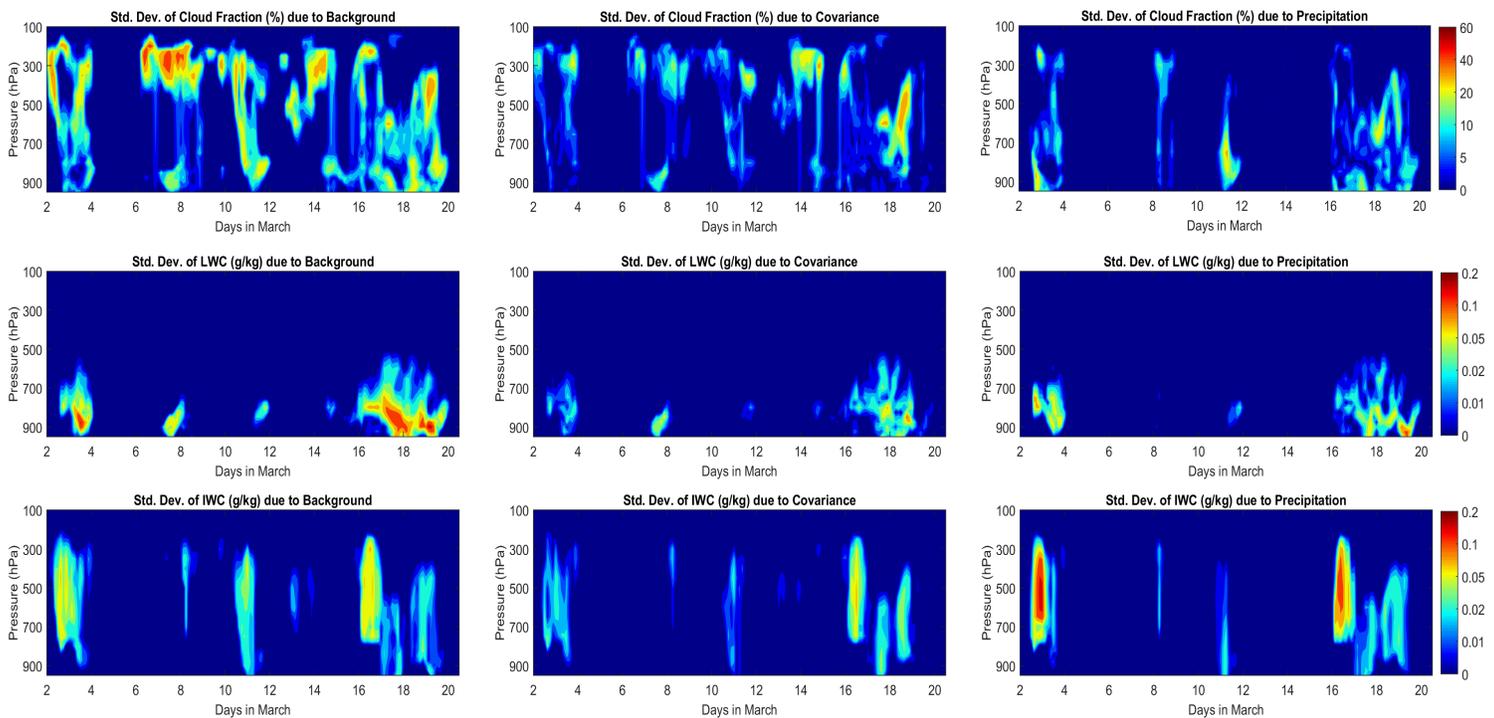

359 Figure 6: the ensemble average of SCAM5 (left) simulated cloud properties and cloud retrievals  
 360 from MICROBASE (right). From top to bottom: cloud fraction, LWC and IWC (model IWC  
 361 includes both cloud ice and snow).

362

363 The standard deviations of simulated cloud fraction, LWC and IWC to different  
 364 elements of large-scale forcing data are shown in Figure 7. The uncertainty of cloud  
 365 properties at some time steps could reach up to more than 50% of simulated values,  
 366 implying that the amount of the cloud fraction and hydrometeors is sensitive to the  
 367 initialization of large-scale forcing data. The mean 1-sigma uncertainty is about 25.9%  
 368 for cloud fraction, 17.6% for LWC and 16.1% for IWC. Among the three elements in  
 369 3DCVA, background data are the largest contributor to uncertainties of cloud fraction  
 370 and LWC, which is similar to the results in the previous section. However, IWC is more

371 sensitive to the precipitation rather than to the background data. Further analysis shows  
372 that the cloud ice is more sensitive to the background data, but snow, which is much  
373 larger than cloud ice mixing ratio, is more sensitive to the precipitation. Overall,  
374 different elements in the large-scale forcing data have considerable impacts on SCM  
375 cloud simulation.

376

377

378 Figure 7: the standard deviations of SCAM5 simulated clouds (from top to bottom: cloud fraction,  
379 LWC and IWC) due to different background data (left), error covariance matrices (middle) and  
380 precipitation (right).

381

## 382 4.2 Evaluation of model biases using ensemble simulations

383 In SCMs, model errors come from two sources: deficiencies in physical  
384 parameterizations and uncertainties in large-scale forcing data. By considering

385 uncertainties in both large-scale forcing data and observed validation data, we can better  
386 identify the source of model bias (discrepancy between models and observations):  
387 whether the model bias can be explained by the uncertainties in forcing data and observed  
388 validation data, or if it comes from physical parameterizations (true model errors).

389 In this study, the model uncertainties due to large-scale forcing data are estimated  
390 as twice of the model standard deviation (2-sigma uncertainty) using different large-scale  
391 forcing data from all 90 3DCVA members listed in Table 1. The uncertainties in the  
392 MICROBASE cloud retrievals are estimated as 15% for LWC, 55% for IWC and 25%  
393 for cloud fraction. These numbers are based on the study by *Zhao et al.* [2014] in which  
394 they perturbed key inputs and parameters in cloud retrieval algorithms and estimated  
395 these uncertainties. Limitations and caveats about the cloud retrievals will be discussed  
396 later.

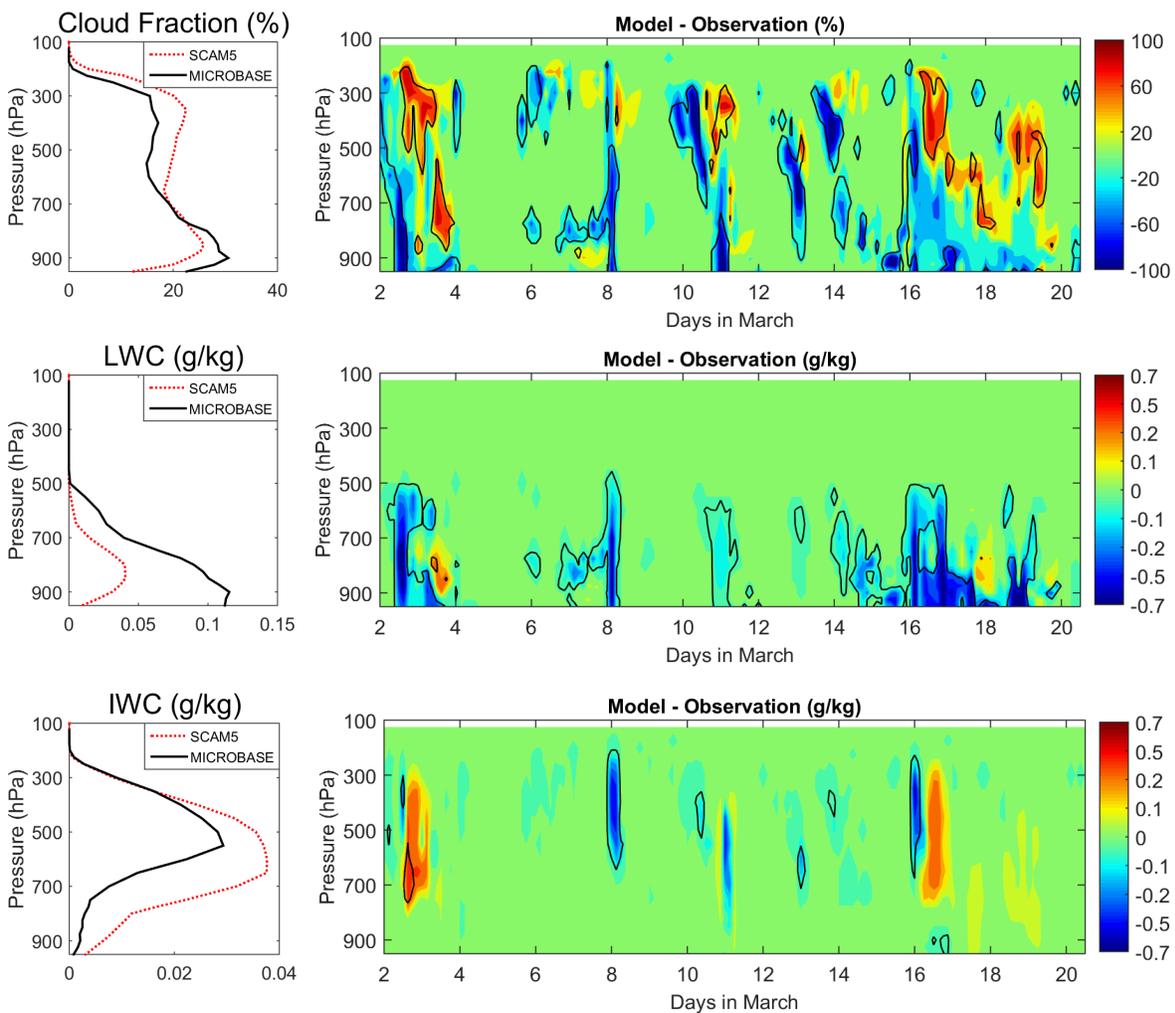

397 Figure 8 shows the model bias of cloud fraction, LWC and IWC in time-pressure  
398 profiles (right), and the vertical profiles averaged in the whole period (left). The black  
399 lines in the right panel highlight regions where model biases are larger than the  
400 uncertainties from forcing data and observations:

$$401 \quad |SCAM5 - MICROBASE| > \sqrt{(2\sigma_{forcing})^2 + \sigma_{obs}^2} \quad (6)$$

402 where  $\sigma_{forcing}$  is the 1-sigma uncertainty of SCAM5 simulations due to different forcing  
403 data, and  $\sigma_{obs}$  is the observation uncertainty specified above. It is seen that SCAM5  
404 overestimates high-cloud while underestimates low-cloud, consistent with its  
405 overestimation of IWC and underestimation of LWC. Most of these biases are

406 significantly larger than the total uncertainties from large-scale forcing data and  
 407 observations, indicating that these biases are due to the deficiencies of physical  
 408 parameterizations in the model. For IWC, most of the model overestimation is within the  
 409 uncertainties from large-scale forcing data and observations.

410

411

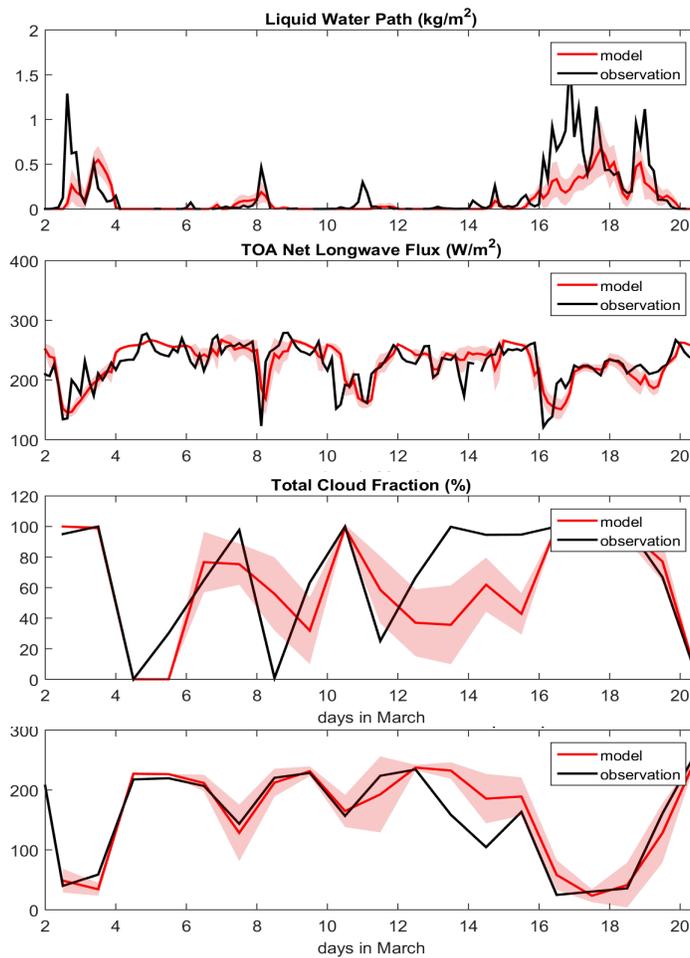

412 Figure 8: (right) SCAM5 model bias of cloud properties. Blue color means model  
 413 underestimation while yellow/red means overestimation, with black lines circle out where model  
 414 bias is larger than the total uncertainties from large-scale forcing data and observations. (left)  
 415 vertical profiles averaged during the whole period. Black line is MICROBASE, red dashed line  
 416 is SCAM5. From top to bottom: cloud fraction, LWC and IWC (IWC includes both cloud ice and  
 417 snow).

418

419           The uncertainties of the cloud hydrometeor retrievals given above could be  
420 underestimated. *Zhao et al.* [2014] pointed out that when considering all assumptions  
421 and for precipitating clouds, uncertainties could be larger than those given in this study.  
422 The spread among different products may be much larger than the diagnosed  
423 uncertainties [*Zhao et al.*, 2012]. Later analysis will also show this large spread (Figure  
424 10). *Huang et al.* [2012] suggests that different input data, different treatments of rain  
425 contamination and mixed-phase clouds are mainly responsible for the large differences of  
426 retrieved LWC.

427           Given the large uncertainties in the cloud retrievals, it is important to examine if  
428 model errors shown in cloud properties are consistent with those exhibited in other  
429 relevant fields. Figure 9 compares the LWP, outgoing long wave flux at TOA, total cloud  
430 fraction (daytime mean) and surface downward shortwave flux (daily mean) between the  
431 observations (ARMBE) and SCAM5 simulations. The standard deviations of model  
432 simulations due to different forcing data are shown in the shaded area. The use of daily  
433 averaging for the surface downward shortwave flux is to remove the strong diurnal cycle  
434 and the use of daytime averaging for the total cloud fraction is to make it consistent with  
435 surface downward shortwave flux because there is no shortwave flux at nighttime. The  
436 time variations of these variables are overall consistent with cloud fraction and  
437 hydrometeors during this period.

438

439

440 Figure 9: Ensemble mean SCAM5 simulations (red line) with standard deviations due to different  
 441 large-scale forcing data (red shade) and observations from ARMBE (black). From up to bottom:  
 442 LWP, TOA net longwave flux, total cloud fraction (daytime mean) and surface downward  
 443 shortwave flux (daily mean).

444

445 It can be seen that the LWP in SCAM5 is lower than the observed value during  
 446 most of cloud/precipitation events. The simulated LWP (with standard deviation, same  
 447 as below) averaged during the whole IOP is  $94.8 \pm 6.9 \text{ g m}^{-2}$ , comparing to the observed  
 448  $191.3 \text{ g m}^{-2}$ . Note that LWC in MICROBASE has been constrained by the LWP at the  
 449 SGP central facility so the LWC and LWP are not independent. We therefore examine

450 the radiation fields at the TOA and surface, which are independent with the retrieved  
451 cloud properties.

452 For longwave flux at TOA, SCAM5 missed some cloud events on 10 and 14  
453 March, where longwave flux has a sharp decrease in the observations but is relatively flat  
454 in the model. During the whole IOP, SCAM5 has TOA longwave flux of  $229.4 \pm 1.1 \text{ W m}^{-2}$   
455  $\text{m}^{-2}$ , slightly larger than the observed  $227.6 \text{ W m}^{-2}$ . However, the model does not always  
456 overestimate longwave flux at TOA. During times when SCAM5 has more high cloud  
457 fraction than observations in Figure 8, it also underestimates longwave flux (on 3, 17  
458 and 19 March).

459 For total cloud fraction and surface downward shortwave flux, daily (daytime)  
460 averaging is used to smooth out some short-period cloud features. From 13 to 15 March,  
461 the model overestimation of surface downward shortwave fluxes is consistent with the  
462 underestimation of total cloud fraction. These consistencies between the biases of cloud  
463 properties with biases of radiation fluxes give us more confidence in attributing model  
464 biases to the deficiencies of physical parameterizations.

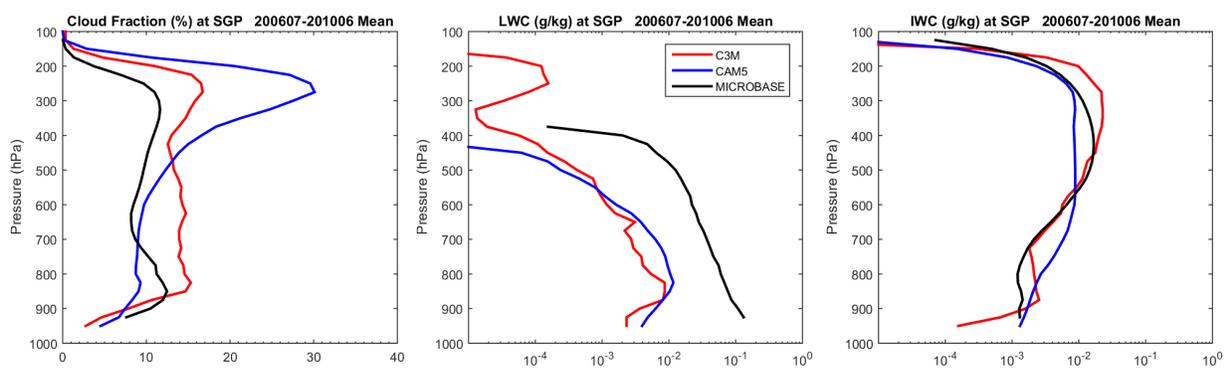

#### 465 4.3 Applicability of SCM results to GCM

466 The above analysis of model biases is limited to one single IOP. To understand  
467 the applicability of the SCM results in this IOP to the GCMs climatologically and  
468 globally, we compare the simulations of clouds in the global CAM5 with satellite cloud  
469 retrievals C3M to examine if the biases in SCAM5 still exist in CAM5 GCM.

470 Figure 10 shows the climatological mean cloud fraction, LWC and IWC at SGP  
471 site (or the nearest grid) from CAM5 (blue), C3M (red) and MICROBASE (black),

472 respectively. For cloud fraction, both the C3M and MICROBASE data show that CAM5  
 473 overestimates high clouds and underestimates low clouds, which is consistent with  
 474 SCAM5 results discussed earlier. For LWC, the differences between the two  
 475 observations are too larger to draw a firm conclusion about the CAM5 GCM (note that  
 476 the x axis is in logarithm scale). The reason of large LWC differences between C3M and  
 477 MICROBASE remains unclear. One possible cause is the different assumptions used in  
 478 the retrieval algorithms, where C3M assumes all clouds are liquid (ice) phase when  
 479 retrieving LWC (IWC), while MICROBASE assumes cloud droplets number  
 480 concentration is constant ( $100 \text{ cm}^{-3}$ ). The different angles of measurements could be  
 481 another reason, where C3M satellite radar is more affected by the high clouds, which  
 482 corresponds to the large LWC at  $\sim 200$  to  $300 \text{ hPa}$ . The CAM5 GCM is closer to the  
 483 C3M profile than to the MICROBASE data below  $400 \text{ hPa}$ . For IWC, the differences  
 484 among the two observations and model are relatively small.

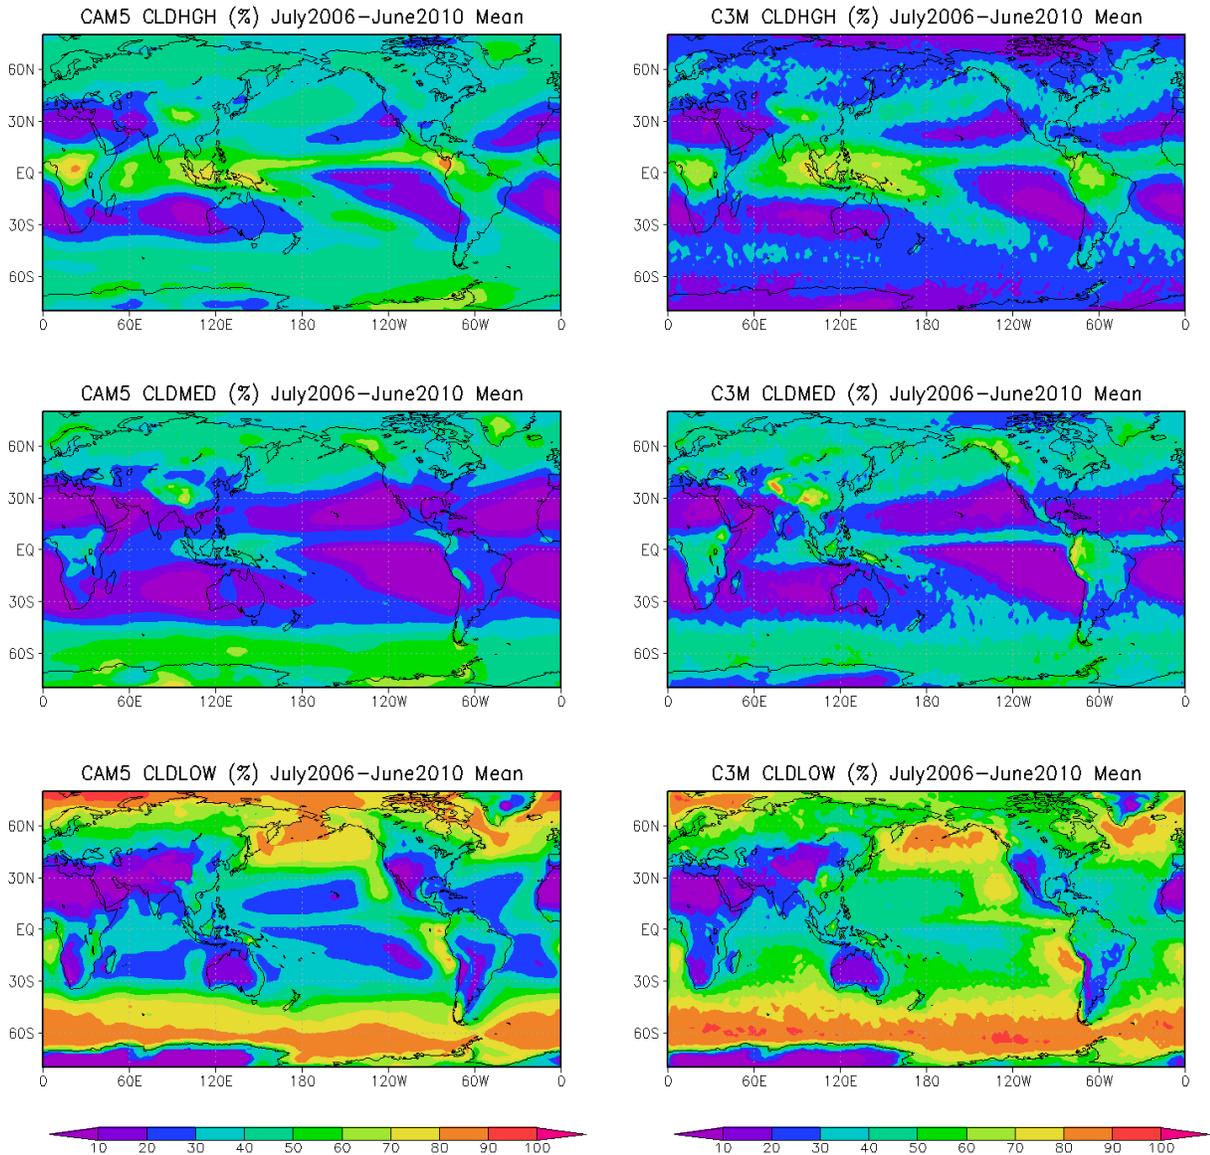

485

486

487 Figure 10: 4-year (July 2006 to June 2010) mean profiles of cloud fraction (left), LWC (middle)  
 488 and IWC (right) at SGP site or the closest grid. Blue line is from CAM5 GCM, red line is from  
 489 C3M merged satellite retrieval, black line is from MICROBASE ground retrieval.

490

491

492 Figure 11: 4-year (July 2006 to June 2010) mean total high- (top), middle- (middle) and low-  
 493 (bottom) cloud fraction in CAM5 GCM (left) and C3M merged satellite retrieval (right).

494

495 Despite the large uncertainties in cloud retrievals of LWC and IWC, the model  
 496 biases of the underestimation of low cloud fraction and overestimation of high cloud  
 497 fraction in SCAM5 are valid in the CAM5 GCM at SGP from using both satellite-based

498 and ground-based datasets. Therefore, we only compare cloud fractions in CAM5 and  
499 C3M for the global distribution of clouds. The high-, mid- and low-cloud fractions from  
500 CAM5 and C3M are shown in Figure 11. CAM5 overestimates high-cloud especially in  
501 mid- to high-latitude. For mid-cloud, it simulates more clouds in high-latitude but less in  
502 the tropics. For low-cloud, CAM5 significantly underestimates cloud fraction over  
503 tropical oceans. The global mean fraction of high-, mid- and low-clouds in CAM5 is  
504 38.0%, 26.8% and 43.8%, respectively, comparing to 30.2%, 28.4% and 50.3% in C3M.  
505 These model biases are overall consistent with SCM and GCM biases at SGP that were  
506 described before.

507

## 508 **5. Summary and Discussion**

509 Background data, error covariance matrix and constraint variables are three  
510 important sources of uncertainties (elements) in 3DCVA to derive the large-scale forcing  
511 data required by LES/CRM/SCM. We described an ensemble approach of 3DCVA using  
512 six background data, five error covariance matrices and three constraint variables  
513 (precipitation), in total 90 members. The ensemble approach quantifies the uncertainties  
514 of the large-scale forcing data. The results show that all the three elements of the  
515 ensemble 3DCVA have considerable impact to the analyzed large-scale forcing data,  
516 especially to the vertical velocity and advective tendencies. Among the three elements,  
517 background data have the largest impact on the forcing data, while precipitation has  
518 relatively larger impact to the horizontal moisture advection.

519           With the uncertainty from the large-scale forcing data calculated and the  
520 uncertainty of observed clouds estimated, this study compared the simulated clouds in the  
521 SCAM5 with MICROBASE cloud retrievals. We found that SCAM5 overestimates high-  
522 clouds while underestimates low-clouds, and it underestimates LWC but overestimates  
523 IWC slightly. It also misses some cloud events. Most of these model biases are larger  
524 than the uncertainty from large-scale forcing data plus uncertainty from observations,  
525 indicating that these biases are “true” model errors. These cloud biases are shown to be  
526 consistent with the model biases of surface and TOA radiative fluxes.

527           The applicability of the SCM results at the SGP in the March 2000 IOP to the  
528 global model is examined by comparing CAM5 GCM results with the C3M satellite  
529 retrievals. We show consistent model biases in cloud fraction: CAM5 overestimates high  
530 clouds and underestimates low clouds. These results indicate that most of the GCM  
531 biases are caused by physical parameterizations rather than large-scale dynamics, and that  
532 the SCM simulations forced by the ensemble large-scale forcing data can be used to  
533 further diagnose the cause of model errors in its physical parameterizations.

534           While the ensemble forcing provides a way to estimate the uncertainties in the  
535 large-scale forcing data, we point out that the specified uncertainties in the 3DCVA can  
536 be improved. This is especially true for the uncertainties in the input data of the  
537 constraint variables. The current method only uses uncertainties in the precipitation  
538 constraint that is scaled against the best estimate precipitation. More sophisticated  
539 specification requires knowledge of the spatial structure of the precipitation uncertainties  
540 as well as uncertainties in other constraint variables. With this caveat in mind, we  
541 believe the variationally constrained ensemble of large-scale forcing data described in

542 this paper can be used to more confidently identify and quantify model errors from  
543 LES/CRM/SCM.
