27 **Abstract**

28 Compacted clays are considered as excellent candidates for barriers to radionuclide transport  
29 in future repositories for nuclear waste due to their very low hydraulic permeability.  
30 Diffusion is the dominant transport mechanism, controlled by a nano-scale pore system.  
31 Assessment of the clays' long-term containment function requires adequate modelling of  
32 such pore systems and their evolution. Existing characterisation techniques do not provide  
33 complete pore space information for effective modelling, such as pore and throat size  
34 distributions and connectivity. Special network models for reactive transport are proposed  
35 here using the complimentary character of the pore space and the solid phase. This balances  
36 the insufficient characterisation information and provides the means for future mechanical-  
37 physical-chemical coupling. The anisotropy and heterogeneity of clays is represented using  
38 different length parameters and percentage of pores in different directions. Resulting  
39 networks are described as mathematical graphs with efficient discrete calculus formulation of  
40 transport. Opalinus Clay (OPA) is chosen as an example. Experimental data for the tritiated  
41 water (HTO) and U(VI) diffusion through OPA are presented. Calculated diffusion  
42 coefficients of HTO and uranium species are within the ranges of the experimentally  
43 determined data in different clay directions. This verifies the proposed pore network model  
44 and validates that uranium complexes are diffusing as neutral species in OPA. In the case of  
45 U(VI) diffusion the method is extended to account for sorption and convection. Rather than  
46 changing pore radii by coarse grained mathematical formula, physical sorption is simulated in  
47 each pore, which is more accurate and realistic.

48 **Keywords:** Reactive transport, pore network model, Opalinus Clay, pore shapes

## 49 **1 Introduction**

50 Simulation of reactive transport in both natural (soils, rocks, etc.) and industrial (concrete,  
51 bioengineered tissues, etc.) porous media is highly important to a variety of scientific and  
52 engineering applications [1-4]. These include environmental contaminant transport [1],  
53 carbon dioxide (CO<sub>2</sub>) storage [2], bioremediation [4], and stimulation of petroleum reservoirs  
54 [5]. Most applications require further understanding of multiple processes (diffusion,  
55 convection, and reaction) and scales (microscopic and macroscopic). Because continuum  
56 reactive transport models involve averaging over length scales much larger than typical grain  
57 sizes, they are unable to resolve heterogeneity at smaller scales. This heterogeneity has been  
58 found important for reactive transport modelling at larger scales [6]. Progress can be achieved  
59 by developing physically based and microstructure-informed models suitable for such  
60 analyses. Key initial requirement is that such models are able to predict measurable transport  
61 properties at a macro-scale (engineering, geological) from measurable pore space  
62 characteristics describing structures at a meso-scale (tens of inter-pore distances).

63

64 Pore network models (PNM) are amongst the appealing approaches that provide a suitable  
65 description of mutable pore space structures. Such models have been used to describe  
66 conservative as well as reactive transport in saturated [7] or multiphase and unsaturated  
67 porous media [8, 9]. Moreover, their use has been expanded to complement the application of  
68 percolation theory to porous media [10] and to simulate the effect of microbial growth on  
69 substrate transport and system permeability [4]. The pore space is approximated by a set of  
70 sites and a set of bonds connecting some of the sites. The sites positions may form a regular  
71 lattice (regular PNM) or reflect known length variations (irregular PNM). Mass transport is  
72 allowed through the system of bonds.

73

74 Conceptually, PNM are scale indifferent, i.e. they can be applied to any length-scale interval  
75 where the structure of the pore space has been experimentally characterised. For example, if a  
76 particular experimental technique allows for characterising pore features of sizes between  
77 0.1  $\mu\text{m}$  and 10  $\mu\text{m}$ , then the corresponding PNM will take these into account. The elements  
78 of PNM, sites and bonds, are abstract and can be related to the measurable features in  
79 different ways depending on the available information.

80

81 Historically, pores were related to the sites and pore throats were related to the bonds of  
82 regular PNM [11-13]. If such correspondence is to be statistically representative of the  
83 material modelled, then sufficiently rich experimental information is required: shape and size  
84 distribution of pores and throats, as well as the pore coordination spectrum, i.e. percentages  
85 of pores coordinated by different numbers of throats [13, 14]. These can be obtained from  
86 structures with distinguishable pores and pore throats. One established way is analysing 3D  
87 images from synchrotron X-ray tomography [15, 16].

88

89 It is worth mentioning, that 3D images can be used directly to construct irregular PNM [17].  
90 These allow for validating physical assumptions for flow simulations using 4D imaging of  
91 mass transport. However, such irregular PNM are sample-specific and potentially not  
92 statistically representative. A regular PNM constructed within a larger volume allows for  
93 capturing statistics from a number of imaged samples, i.e. improved statistical  
94 correspondence, and for calculating transport at distances closer to the engineering  
95 application length scale.

96

97 X-ray computed tomography is presently limited to resolving macro-porosity (features larger  
98 than 50 nm). However, the resolution of this experimental technique is not sufficient to  
99 identify throats for systems dominated by meso-porosity (features between 5 nm and 50 nm)  
100 and micro-porosity (features smaller than 5 nm). For pore network construction, this means  
101 that pore connectivity data cannot be extracted as throats cannot be identified.

102

103 One possibility is to develop a regular PNM with pores from experimental distribution  
104 located at sites and notional throats between each pair of neighbouring pores [1] based on a  
105 topologically proper lattice proposed by Jivkov *et al.* [13]. Such a construction allows for the  
106 calculation of the lattice length scale from known porosity and pore size distribution, but the  
107 pore connectivity is constant. The diffusivity of a notional throat depends on the sizes of the  
108 connected pores, the size of the solute molecules, and the interaction of the solute with the  
109 pore walls. The approach provided insights into the effects of pore size distribution, solute  
110 size, and sorption on diffusivity [1]. It was noted, however, that the spatial randomness of  
111 pore sizes yielded variation of calculated diffusion coefficient larger than experimentally  
112 measured variability. This indicated that in the real material there was a strong connectivity  
113 effect, missed by the model due to lack of detailed information. In addition, diffusivity

114 anisotropy emerging from material texture (preferred mineral orientations) could not be  
115 captured.

116

117 Another possibility is to assume variable connectivity [18]. While this was more realistic in  
118 terms of pore space topology, the observable data were insufficient to establish rigorously a  
119 lattice length scale. With variable length scales, improved agreement with the variability in  
120 experimentally measured diffusivity was demonstrated, including diffusion anisotropy in clay.

121

122 The two approaches to tackle incomplete pore space information, namely predefined  
123 connectivity for calculable length scale [1], and undetermined length scale for realistic  
124 connectivity [18], suffer from the lack of an additional constraint. This cannot be found  
125 within the pore space information and requires the consideration of the solid phase structure,  
126 e.g., the shape and size distribution of mineral grains. A methodology for incorporating the  
127 structure of the solid phase is proposed here. It improves substantially the realism of the  
128 constructed PNM, both in terms of geometry and topology. The proposal has added benefit  
129 that the constructed PNM can be paired directly to lattice models of the solid phase  
130 developed for analysis of damage evolution via micro-cracking [19-21]. This facilitates  
131 mechanistic investigations of combined mechanical-thermal-chemical-biological effects on  
132 diffusivity, which will be discussed further in the paper.

133

134 Typical pore network models idealise the pore space with simple geometries, i.e. throats are  
135 assumed to have square or circular cross sections. This makes it difficult to simulate  
136 processes like sorption, which may change pore geometries by physical clogging. Recent  
137 advances allowed to model pore geometries with irregular cross sectional shapes [8]. The  
138 influence of cross sectional shapes on diffusion and sorption will be analysed in this work.

139

140 For safety assessment of repositories for high-level nuclear waste, in particular the migration  
141 behaviour of radioisotopes with long half-lives (e.g.,  $^{238}\text{U}$ ,  $\tau_{1/2} = 4.468 \times 10^9$  a; main fraction of  
142 spent nuclear fuel) is in the focus of research. Opalinus Clay (OPA) is discussed as potential  
143 host rock for nuclear waste repositories, where it is considered as one of the barriers to  
144 radionuclide transport, because it exhibits very low hydraulic conductivity [22]. This makes  
145 molecular diffusion the main transport mechanism of radionuclides through the barrier. In the  
146 present work, OPA is selected to demonstrate the development of the new pore network  
147 model. The pore space information for model construction is adopted from Keller *et al.* [23,

148 24] and Nagra [22]. Validation data on macroscopic diffusivities come from [25-28].  
149 Although OPA has a very low permeability, the effects of velocities on mass transport are  
150 also analysed to demonstrate how the methodology will be applied to other porous media. In  
151 the diffusion experiments so far the neutral  $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$  complex was assumed to be  
152 the main diffusing species through OPA [25], because it was spectroscopically verified to be  
153 the dominant U(VI) species in the experimental source reservoir solution. The model  
154 described in the present study shall clarify whether U(VI) diffuses as cationic, anionic, or  
155 neutral species through OPA.  
156

157 **2 Geometric modelling and data**

158

159 **2.1. Cellular basis for pore network construction**

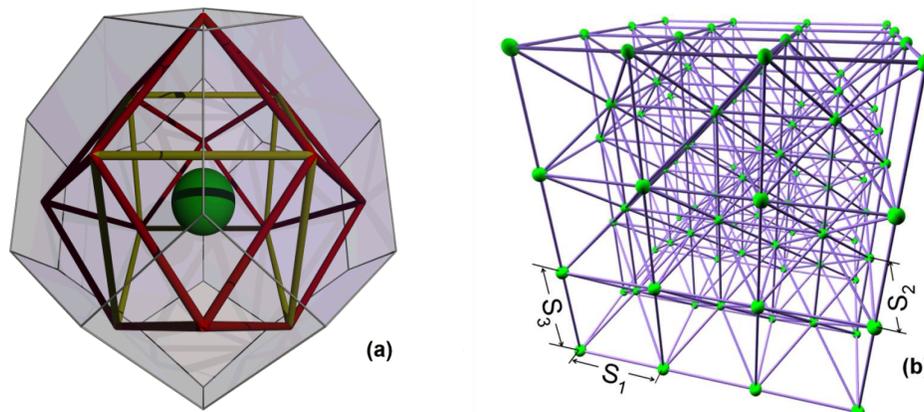

160

161 Statistical analysis of the neighbourhoods of arbitrary features, randomly distributed in 3D  
 162 space, has shown that the truncated octahedron represents the average neighbourhood [29].  
 163 The truncated octahedron was the unit cell of a regular space tessellation, representing the  
 164 neighbourhood of one type of measurable feature, a solid particle [20] or a pore [13], which  
 165 has been used to analyse deformation and failure of quasi-brittle media [19, 30, 31] and  
 166 transport in porous media [1, 18], respectively. Considering the need to couple the  
 167 deformation and the transport models in the future, we choose the truncated octahedron as  
 168 cellular basis for network construction. This has six square faces normal to three  
 169 perpendicular directions, say  $(1, 0, 0)$ ,  $(0, 1, 0)$ , and  $(0, 0, 1)$ , and eight hexagonal faces  
 170 normal to the corresponding octahedral directions,  $(\pm 1, \pm 1, \pm 1)$ .

171

172 The material is reduced to a mathematical graph by placing particles or grains at cell centres  
 173 (interiors). This is illustrated in Fig. 1(a) for cells with equal distances between the three pairs  
 174 of square faces, a setup used in the previous works. In order to represent texture anisotropy,  
 175 three different length parameters,  $S_1$  [m],  $S_2$  [m], and  $S_3$  [m], are used to measure the  
 176 distances between the square faces in directions  $(1, 0, 0)$ ,  $(0, 1, 0)$ , and  $(0, 0, 1)$ , respectively.  
 177 All other distances are then dependent on the three length parameters, e.g., the volume of  
 178 each cell is  $V_c = S_1 S_2 S_3 / 2$  [m<sup>3</sup>].

179

180

181 Fig. 1: Pore space representation: (a) unit cell illustrating potential diffusion paths (bonds,  
 182 yellow and red) in the neighbourhood of central particle (green); these join neighbouring cell

183 faces and show where elongated pores may be assigned to the experimental pore system  
 184 information; (b) a fragment of a lattice model for deformation and failure analysis, illustrating  
 185 sites on particles and bonds between neighbouring particles.

186

187 In an assembly of  $N_c$  [-] cells, each cell is assigned to a particle with different radius,  $r_i$  [m].  
 188 The assignment of particles terminates when their accumulated volume fraction equals to the  
 189 experimentally measured value. From this requirement the volume of a cell assembly is  
 190 calculated by:

$$191 \quad V_c = \frac{1}{\phi N_c} \sum_{i=1}^{N_c} \frac{4\pi r_i^3}{3} \quad \left( = \frac{1}{2} S_1 S_2 S_3 \right) \quad (1)$$

192 where  $\phi$  [-] is the measured volume percentage of particles. The calculation of the three  
 193 length parameters from Eq. (1) depends on the selection of their ratios used here to represent  
 194 texture. A non-textured medium has  $S_1 = S_2 = S_3$ .

195

196 Each particle (site, cell centre) is connected to its 14 neighbouring particles by bonds  
 197 representing relative deformations between cells, illustrated in Fig. 1(b). This graph can be  
 198 analysed very efficiently using discrete exterior calculus to investigate the response of the  
 199 material to loading, including micro-crack generation, competition, and coalescence [32]. The  
 200 presence of pores in cell neighbourhoods is reflected in pore-size-dependent reduction of  
 201 bond strengths. Further, the assigned particle sizes may also contribute to spatial variation of  
 202 bond properties within the model. However, for the construction of the PNM the particular  
 203 particle sizes do not play a role; only the length parameter calculated by Eq. (1) is of essence.

204

205 The pore network construction is as follows. Firstly, a new skeleton is formed using sites at  
 206 the centres of cell faces and bonds between neighbouring faces. This is illustrated in Fig. 1(a)  
 207 on a single cell with  $S_1 = S_2 = S_3$  for clarity. The bonds represent potential transport pathways,  
 208 i.e. they show the positions where elongated pores are allowed to reside. Note that there are  
 209 no bonds cutting through cells, hence the pore system can follow paths around particles. The  
 210 elongated pores can be assigned with different cross sectional shapes, such as circular,  
 211 equilateral, and square. Since pores reside on bonds, the sites at face centres represent pore  
 212 junctions – volume-less containers redirecting mass transport.

213

214 Notably, this skeleton allows for pores with maximum coordination of 8 or 12 depending on  
215 whether the bond connects square to hexagonal or hexagonal to hexagonal boundary.  
216 Importantly, the length parameters of the skeleton, determining the lengths of possible pores,  
217 are now dictated by the solid phase structure.

218

## 219 **2.2. Pore shape**

220

221 A key characteristic of real porous media is the angular form of pores. It has been  
222 demonstrated that having pores with a circular cross section, and thus single-phase occupancy,  
223 causes insufficient connectivity of the wetting phase and as a result poor representation of  
224 experimental data [33]. Angular cross sections retain the wetting fluid in their corner and  
225 allow two or more fluids to flow simultaneously through the same pore. Pores which are  
226 angular in cross section are thus a more realistic model than the commonly employed  
227 cylindrical shape. The shape of an angular pore cross section is prescribed in terms of a  
228 dimensionless shape factor,  $G$ , which is defined as

$$229 \quad G = \frac{A}{P^2} \quad (2)$$

230 where  $A$  [m<sup>2</sup>] and  $P$  [m] are the area and the perimeter of the cross section [34], respectively.  
231 The shape factor replaces the irregular and complicated shape of a pore by an equivalent  
232 circular, triangle, or rectangle shape. The value of shape factors ranges from a minimum of  
233 zero corresponding to a slit to a maximum of 0.08 corresponding to a circular cross section.  
234 Values of shape factors for triangular cross sections vary from 0 to 0.048 (with maximum for  
235 equilateral triangle), and rectangular cross section from 0 to 0.062 (with maximum for square  
236 shape).

237

## 238 **2.3. Assignment of porosity**

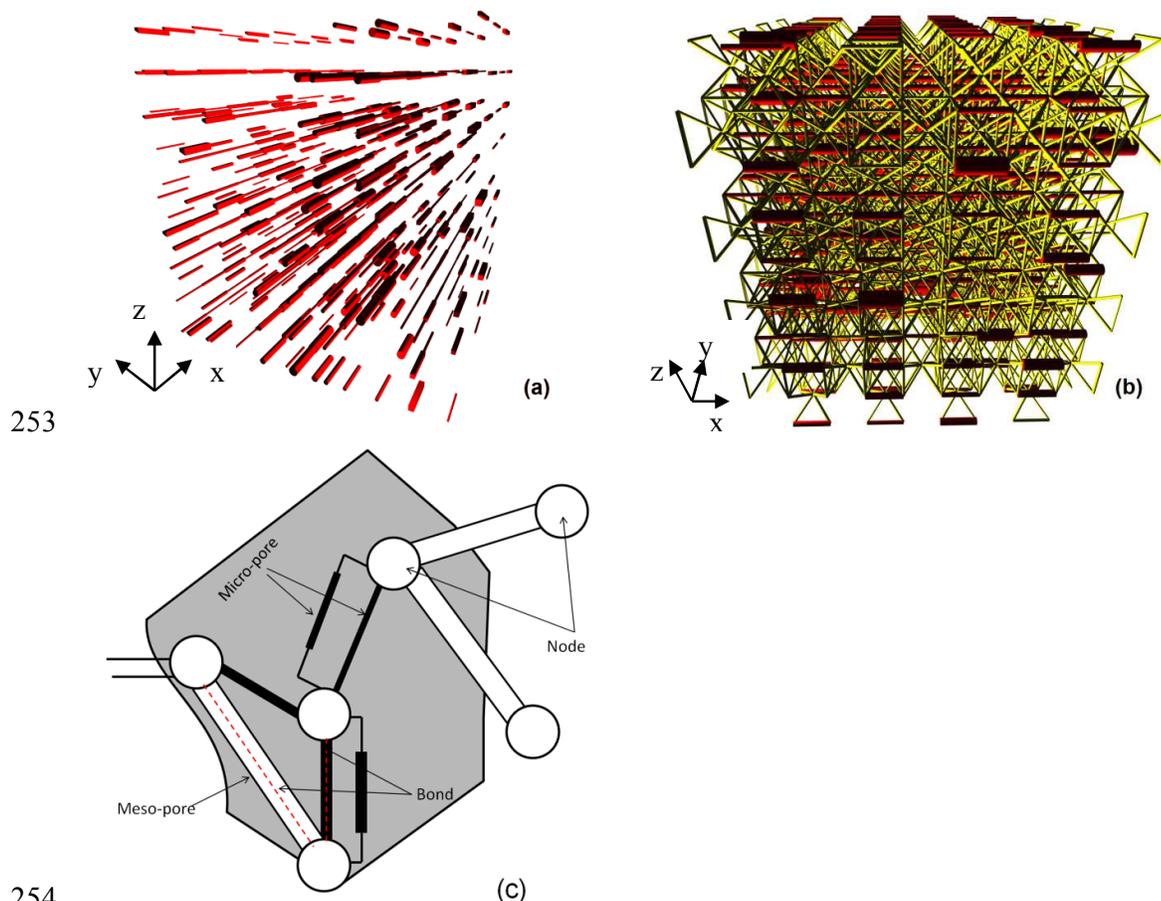

239

240 Pores with the desired characteristics, e.g., porosity and pore size distribution, will be  
241 generated in a particle or grain structure that best represents the measured material's size and  
242 orientation. Usually, the pores in porous material can be divided into several groups, such as  
243 macro-pores, meso-pores, and micro-pores. For example, there exist meso-pores and micro-  
244 pores in the material. Firstly, meso-pores are assigned to available bonds of Fig. 2(a)  
245 according to the experimental data. An available bond is a bond with no previously assigned

246 pore. The volume of all allocated meso-pores is required to equal experimentally determined  
 247 meso-pore volume, i.e. when

$$248 \quad \sum_i V_i = N_c V_c \theta_{mes} \quad (3)$$

249 where  $V_i$  [ $\text{m}^3$ ] is the pore volume,  $\theta_{mes}$  [-] is the volume fraction of meso-pores. The  
 250 assignment of meso-pores can be in different directions or constrained to a selected direction,  
 251 to simulate the anisotropy and heterogeneity. In the selected direction, the pores are randomly  
 252 assigned to bonds. All bonds in the chosen direction are available for meso-pore assignment.

255 Fig. 2: Illustration of pore assignment to diffusion site-bond model: (a) exclusive assignment  
 256 of meso-pores along (1, 0, 0) with different pore cross sectional shapes taken as the clay  
 257 bedding direction; (b) pore network model after assignment of meso-pores (red) and micro-  
 258 pores (yellow) – micro-pores allowed in all directions. Examples are given on lattice with  
 259 equal length parameters for bedding and out-of-bedding directions. (c) Schematic depiction  
 260 of meso-pores and micro-pores assigned to bonds.

261

262 Secondly, micro-pores are assigned to bonds not already occupied by meso-pores. The micro-  
263 pores are also assumed to be of different shape and each new pore assignment increments the  
264 pore volume according to selected cross section area and bond length. The process terminates  
265 when the total pore volume fraction, from meso- and micro-pores, attains the experimental  
266 porosity. Notably, micro-pores are allowed at bonds in all directions, including bonds in the  
267 bedding direction not occupied by meso-pores, and more than one micro-pore can be  
268 assigned to a bond if required to reach prescribed porosity, illustration in Fig. 2(c). A set of  
269 micro-pores assigned to a bond can be considered as providing an “effective” transport  
270 between two pore junctions, which is necessary to create transport paths in the otherwise non-  
271 percolating meso-pore system. Importantly, they act as sieves for transport of species with  
272 different molecular sizes.

273

274 An example of a PNM after assigning meso-pores and micro-pores with different pore shape  
275 sets is shown in Fig. 2(b). The micro-pore sets are presented as bundles with scaled-up cross-  
276 sections and the network is constructed with equal length parameters in the bedding and out-  
277 of bedding directions for improved illustration. In the simulations different length parameters  
278 in bedding and out-of bedding directions were used to represent texture.

279

#### 280 **2.4. Experimental characterisation data**

281

282 OPA has anisotropic transport properties due to preferred orientation (or texture) of clay  
283 minerals attained during sedimentation and compaction [35]. Specifically, solute species  
284 diffuse slowly perpendicular and fast parallel to the bedding plane. Our goal is to construct a  
285 regular PNM, which calculates diffusion in line with macroscopic observations, and can be  
286 linked to models for deformation and failure of the solid phase, based on available structural  
287 data.

288

289 Regarding the pore space, we make use of the 3D analysis of OPA reported by Keller *et al.*  
290 [23, 24] and Nagra [22]. The pore space was divided into meso-pores and micro-pores based  
291 on the resolution of different experimental techniques in our work. The meso-pores were  
292 resolved by Focused Ion Beam nano-tomography (FIB-nt) with elongated pores in the  
293 bedding plane. These pores had approximately cylindrical shapes with diameters  $> 10$  nm and  
294 were largely isolated (i.e. solute species cannot percolate through the sample). The meso-  
295 pores occupied approximately 1.8 vol.% of the sample, i.e. their volume density (porosity)

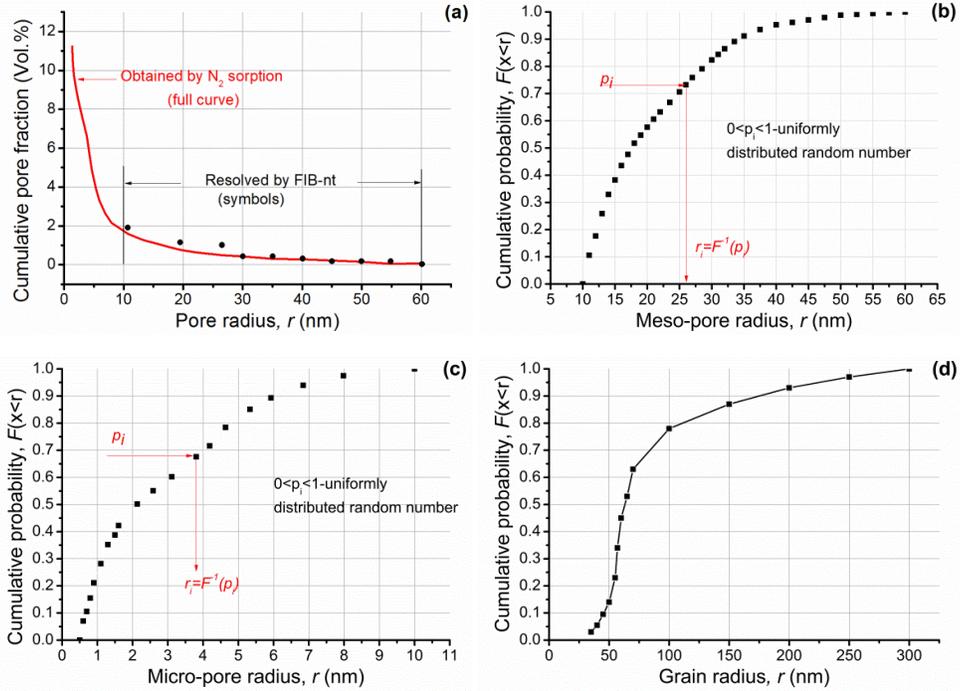

296 was  $\theta_{mes} = 0.018$ . The micro-pores were resolved by N<sub>2</sub> adsorption with pore sizes < 10 nm,  
297 but were unresolved by FIB-nt. The analysis of N<sub>2</sub> adsorption gave a total physical porosity  
298 of around 11.5 vol.%, of which 9.7 vol.% were micro-pores. The volume density of micro-  
299 pores is thus  $\theta_{mic} = 0.097$  [23]. However, micro-pores narrower than 2 nm cannot be probed  
300 by N<sub>2</sub> adsorption. For OPA from Mont Terri, most estimates of the total porosity are on the  
301 order of 16 vol.% [25, 36, 37]. In this work, we assume that micro-pores smaller than 2 nm  
302 occupy 4.5 vol.% and follow the same distribution as pores occupying 9.7 vol.%. These  
303 measurements show that the fine-grained clay matrix contains an extensive micro-pore  
304 network. The meso-pore system can be seen as part of the effective “flow relevant” porosity  
305 that surrounds the clay mineral particles and is interconnected by micro-pores.

306

307 The two measurements were combined into a single “cumulative pore volume fraction – pore  
308 radius” curve given in Fig. 3(a) [18, 23]. This shows that the geometrically resolved meso-  
309 pores (symbols) and the adsorption-based curve coincide in their common length interval,  
310 with meso-porosity  $\theta_{mes} = 0.018$  and total porosity  $\theta = 0.16$ . The radii are derived with the  
311 assumption of cylindrical pore shapes truthful to experimental evidence for meso-pores [23]  
312 and approximate for micro-pores. For the purpose of model construction the experimental  
313 distribution from Fig. 3(a) is re-evaluated as cumulative probability separately for meso- and  
314 micro-pores. These are shown in Fig. 3(b) and Fig. 3(c), respectively. The use of the  
315 cumulative probability is to produce sizes from the measured distribution in Fig. 3(a) using a  
316 generator for uniformly distributed numbers  $0 \leq p < 1$ . This is illustrated by the red arrows on  
317 Figs. 3(b) and 3(c); more details on statistics are given by Jivkov and Xiong [18]. For pores  
318 with other shapes such as square, the radii are converted to length of side with equal pore  
319 volume.

320

321 Regarding the structure of the solid phase, Keller *et al.* [24] reported 18 vol.% of non-porous  
322 carbonates and 17 vol.% of non-porous quartz in the sample. The sizes of carbonates ranged  
323 from 100 to 300 nm, while the size distribution of quartz was not measured. The reported  
324 data of carbonate were converted to the cumulative probability of its grain sizes shown in Fig.  
325 3(d) for model construction. The same cumulative probability is assumed for the non-porous  
326 quartz, due to the lack of more accurate data, and used to generate particle sizes of both types  
327 in a way similar to pore size generation.

328

329

330 Fig. 3: Microstructure characteristics of OPA: (a) cumulative pore volume fraction versus  
 331 pore size determined by FIB-nt and  $N_2$  adsorption analyses [23]; (b) cumulative distribution  
 332 of meso-pore sizes; (c) cumulative distribution of micro-pore sizes with assumed probability  
 333 density from [18]; (d) cumulative distribution of carbonate grain sizes [24].

334

### 335 3 Transport modelling and data

336

#### 337 3.1. Diffusion equation

338 The driving force for local diffusion is the concentration gradient between connected nodes  
 339 with resistance provided by the pores. In reality, pores have different shapes. However, the  
 340 experimental data of cumulative pore fraction from Keller *et al.* [23] substituted the irregular  
 341 shape of pores by equivalent circular shape. To reflect realistic situation, circularity  
 342 dependent on shape factor is introduced to consider the effect of pore shapes when all pores  
 343 are assumed to be circular [38]. In our work, the pores are considered to be elongated  
 344 conduits with different pore shapes. The diffusive flow,  $F_{ij}$  [kg/s], through a pore is described  
 345 by the Fick's first law

346

$$F_{ij} = 4\pi G_{ij} D_{ij} A_{ij} \frac{c_i - c_j}{l_{ij}} \quad (4)$$

347 where  $D_{ij}$  [ $\text{m}^2/\text{s}$ ] is the pore diffusivity, which is calculated in the same way as in Xiong *et al.*  
 348 [1, 39],  $A_{ij}$  [ $\text{m}^2$ ] is the pore cross-section area,  $l_{ij}$  [ $\text{m}$ ] is the pore length,  $c_i - c_j$  [ $\text{kg}/\text{m}^3$ ] is the  
 349 concentration difference between nodes,  $4\pi G_{ij}$  [-] is the circularity.

350

351 To verify the pore network model, two diffusion species are considered in this work. One is  
 352 HTO, a neutral solute with molecular size of  $r_A = 0.1$  nm [18]. The other is a neutral U(VI)  
 353 complex,  $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3$ , which dominates the U(VI) speciation in OPA pore water at room  
 354 temperature to nearly 100 % [40]. The molecular size of this complex is  $r_A = 0.524$  nm [41].  
 355 These two species are selected for comparison with experimental data on their diffusivity in  
 356 OPA. The free molecular diffusion coefficients calculated with the Einstein-Stokes equation  
 357 at room temperature, are  $D_0 = 2.24 \times 10^{-9}$   $\text{m}^2/\text{s}$  for HTO [42] and  $D_0 = 4.66 \times 10^{-10}$   $\text{m}^2/\text{s}$  for  
 358 U(VI) [43], respectively.

359

### 360 3.2. Flow equation

361

362 We assume saturated flow through the network. The flow field in the network is described by  
 363 imposing two different pressures on two opposing boundaries of the network. The remaining  
 364 boundaries of the network do not permit flow. For a pore with area  $A_{ij}$  [ $\text{m}^2$ ] and shape factor  
 365  $G_{ij}$ , connecting nodes  $i$  and  $j$ , the volume flow rate of diffusing species,  $q_{ij}$  [ $\text{m}^3/\text{s}$ ], is described  
 366 by the Hagen-Poiseuille equation

$$367 \quad q_{ij} = m \frac{A_{ij}^2 G_{ij}}{\mu l_{ij}} (p_i - p_j) \quad (5)$$

368 where  $m$  [-] is a pore-shape coefficient (for a circular, an equilateral and a square tube,  $m$  is  
 369 0.5, 0.6, and 0.5623, respectively [44]),  $\mu$  [ $\text{Pa}\cdot\text{s}$ ] is the dynamic viscosity,  $p_i$  and  $p_j$  [ $\text{Pa}$ ] are  
 370 pressures at pore  $i$  and  $j$ , respectively. Eq. (5) is considered to be appropriate for describing  
 371 flow in pores [45] and is valid for laminar flow in a wide range of Reynolds numbers. For  
 372 incompressible, steady state flow, the sum of pore discharges at node must be zero

$$373 \quad \sum_{j=1}^{z_i} q_{ij} = 0 \quad (6)$$

374 where  $z_i$  [-] is the number of pores connected to node  $i$ . Then the average pore water velocity  
 375 through the pore network,  $\bar{v}$  [ $\text{m}/\text{s}$ ], can be determined as

$$376 \quad \bar{v} = \frac{QL}{V} \quad (7)$$

377 where  $Q$  [ $\text{m}^3/\text{s}$ ] is the total discharge through the network;  $L$  [m] is the network length in the  
 378 flow direction;  $V$  [ $\text{m}^3$ ] is the volume of the network.

379

### 380 3.3. Mass transport equation

381

382 The transient dynamics of a solute subject to sorption and transport are described by the  
 383 following equations:

$$384 \quad \frac{\partial c}{\partial t} = \left( \frac{\partial c}{\partial t} \right)_{adv} + \left( \frac{\partial c}{\partial t} \right)_{dif} + \left( \frac{\partial c}{\partial t} \right)_{sorp} \quad (8)$$

$$385 \quad \left( \frac{\partial c}{\partial t} \right)_{adv} = -\nabla(cu) \quad (9)$$

$$386 \quad \left( \frac{\partial c}{\partial t} \right)_{dif} = \nabla D(\nabla c) \quad (10)$$

$$387 \quad L \left( \frac{\partial c}{\partial t} \right)_{sorp} = -\frac{\partial s}{\partial t} \quad (11)$$

388 where  $t$  [s] is time,  $c$  [ $\text{kg}/\text{m}^3$ ] is the concentration of the species in the system,  $u$  [m/s] is the  
 389 fluid velocity vector,  $D$  [ $\text{m}^2/\text{s}$ ] is the diffusion coefficient,  $s$  is the adsorbed mass onto the  
 390 solid phase [ $\text{kg}/\text{m}^2$ ], and  $L$  is the throat length [m].

391

392 A temporal and spatial discretization of above equations is used to describe mass transport  
 393 through a pore

$$394 \quad V_{ij} \frac{dc_{ij}}{dt} = V_{ij} u_{ij} \frac{c_i - c_j}{l_{ij}} + F_{ij} - S_{ij} \frac{ds_{ij}}{dt}. \quad (12)$$

395 Substituting Eq. (4) and (5) into Eq. (12), the mass flow of species in a throat is

$$396 \quad V_{ij} \frac{dc_{ij}}{dt} = q_{ij} (c_i - c_j) + 4\pi G_{ij} D_{ij} A_{ij} \frac{c_i - c_j}{l_{ij}} - S_{ij} \frac{ds_{ij}}{dt}, \quad (13)$$

397 where  $q_{ij}$  [ $\text{m}^3/\text{s}$ ] is the volumetric flow within the throat,  $c_{ij}$  [ $\text{kg}/\text{m}^3$ ] is the average  
 398 concentration in the pore,  $s_{ij}$  [ $\text{kg}/\text{m}^2$ ] is mass adsorbed per unit area of the pore wall,  $S_{ij}$  [ $\text{m}^2$ ]  
 399 is the surface area,  $V_{ij}$  [ $\text{m}^3$ ] is the pore volume [46].

400 Linear equilibrium adsorption is described by:

$$401 \quad s_{ij} = k_{a,ij} c_{ij}, \quad (14)$$

402 where  $k_{a,ij}$  [m] is the distribution coefficient normalized to the surface area ( $k_d/S_{ij}$ ) [47].

403 Then Eq. (13) becomes

404 
$$V_{ij} (1 + k_{a,ij} \beta) \frac{dc_{ij}}{dt} = q_{ij} (c_i - c_j) + 4\pi G_{ij} D_{ij} A_{ij} \frac{c_i - c_j}{l_{ij}}, \quad (15)$$

405 where  $\beta = S_{ij}/V_{ij}$  [1/m].

406 For nonlinear equilibrium adsorption the Freundlich isotherm [48] is used:

407 
$$s_{ij} = a c_{ij}^b, \quad (16)$$

408 leading to

409 
$$V_{ij} (1 + a \beta c_{ij}^{b-1}) \frac{dc_{ij}}{dt} = q_{ij} (c_i - c_j) + 4\pi G_{ij} D_{ij} A_{ij} \frac{c_i - c_j}{l_{ij}}, \quad (17)$$

410 where  $a$  [ $m^{3b-2}/kg^{b-1}$ ] and  $b$  [-] ( $b > 1$ ) are coefficients for sorption.

411

### 412 3.4. Network transport analysis

413

414 The system illustrated in Fig. 2(b) is a 3D mathematical graph – sites are graph nodes, bonds  
415 are graph edges. The graph topological structure (connectivity) is described by the so-called  
416 incidence matrix  $\underline{\mathbf{A}}$  of dimensions  $E \times N$ , where  $E$  is the number of edges (pores) and  $N$  is the  
417 number of nodes (pore junctions). An element of this matrix,  $a_{en}$ , can be either -1, +1, or 0, if  
418 node  $n$  is the first, second or not incident of edge  $e$ .

419

420 The incidence matrix describes both the topological structure of the system, which can be  
421 used for connectivity analysis, and the derivative of a discrete function defined on the nodes  
422 [49]. Specifically, a concentration field on the graph nodes, vector  $\underline{\mathbf{C}}$  of dimension  $N$ , has a  
423 gradient given by the matrix product  $\underline{\mathbf{A}} \underline{\mathbf{C}}$ , which is a discrete field on the edges, vector  $\underline{\nabla \mathbf{C}}$   
424 of dimension  $E$ . As importantly, the transpose of the incidence matrix describes the derivative of  
425 a discrete function defined on the edges. Specifically, a mass flow field on the graph edges, a  
426 vector  $\underline{\mathbf{J}}$  of dimension  $E$ , has a gradient given by  $\underline{\mathbf{A}}^T \underline{\mathbf{J}}$ , which is a discrete field on the nodes,  
427 a vector  $\underline{\nabla \mathbf{J}}$  of dimension  $N$ .

428

429 The components of the discrete field of edge flows,  $\underline{\mathbf{J}}$ , are calculated by Eq. (15) or Eq. (17),  
430 i.e. each component is the edge gradient scaled by an edge weight given by  $W_e = (q_{ij} + D_{ij} A_{ij} /$   
431  $l_{ij}) / (1 + k_a \beta)$  or  $W_e = (q_{ij} + D_{ij} A_{ij} / l_{ij}) / (1 + a c_{ij}^{b-1} \beta)$  for linear and nonlinear sorption at pore scale,  
432 respectively. Clearly, the edge weight depends on the assigned pore radius, velocity in the  
433 pore, selected length scale, radius of diffusing species, and sorption coefficient. For  
434 convenience the edge weights are arranged in a diagonal matrix,  $\underline{\mathbf{W}}$ , of dimensions  $E \times E$ ,

435 where the element in row and column  $e$  is the weight of edge  $e$ . Thus, the discrete flow field  
 436 is given by  $\underline{\mathbf{J}} = -\underline{\mathbf{W}} \underline{\mathbf{A}} \underline{\mathbf{C}}$ .

437

438 The mass transport through the graph is governed by mass conservation at nodes, i.e. the rate  
 439 of change of diffusing species mass at the nodes equals the resultant mass flows through the  
 440 nodes. The latter is the algebraic sum of the flows through adjacent edges, which is the  
 441 divergence of the flow field given by  $\underline{\mathbf{A}}^T \underline{\mathbf{J}}$ . Thus, the process of mass transport through a  
 442 weighted graph is formulated mathematically by

$$443 \quad V_n \frac{d\underline{\mathbf{C}}}{dt} = -\underline{\mathbf{A}}^T \underline{\mathbf{W}} \underline{\mathbf{A}} \underline{\mathbf{C}}, \quad (18)$$

444 where  $V_n$  is the node volume, which can be taken as cell volume,  $t$  is the time. This must be  
 445 supplemented by initial and boundary conditions, similarly to continuum problems, but now  
 446 defined on a discrete set of nodes. It is sufficient to point out that the matrix system of Eq.  
 447 (18), supplemented by initial concentrations at all nodes and prescribed concentrations or  
 448 fluxes at boundary nodes, is solved numerically to find nodal concentrations and boundary  
 449 fluxes at any future time. The simulations terminate when steady-state is reached, i.e. when  
 450 concentrations at all nodes are constant.

451

452 The formulation of flow via discrete analysis on graphs is highly beneficial for incorporating  
 453 system evolution compared to traditional finite element or finite difference formulations.  
 454 Conceptually, it shows the intrinsic relation between the pore space topological structure and  
 455 transport, both described via the incidence matrix. Practically, it differentiates clearly  
 456 between effects of connectivity, captured by the incidence matrix  $\underline{\mathbf{A}}$ , and geometry and  
 457 physics, captured by the edge weight matrix  $\underline{\mathbf{W}}$ . This facilitates the incorporation of potential  
 458 pore space changing mechanisms in a computationally effective way. For example, local pore  
 459 geometrical changes arising from corrosion, sorption, bacterial film growth, deformation, etc.,  
 460 will affect corresponding coefficients of  $\underline{\mathbf{W}}$  only but leave  $\underline{\mathbf{A}}$  constant. Material failures, such  
 461 as micro-cracks, during evolution present a more complex case. These change the  
 462 connectivity, i.e. they alter  $\underline{\mathbf{A}}$ , and introduce geometry and physics for the new edges, i.e.  
 463 modify  $\underline{\mathbf{W}}$ .

464

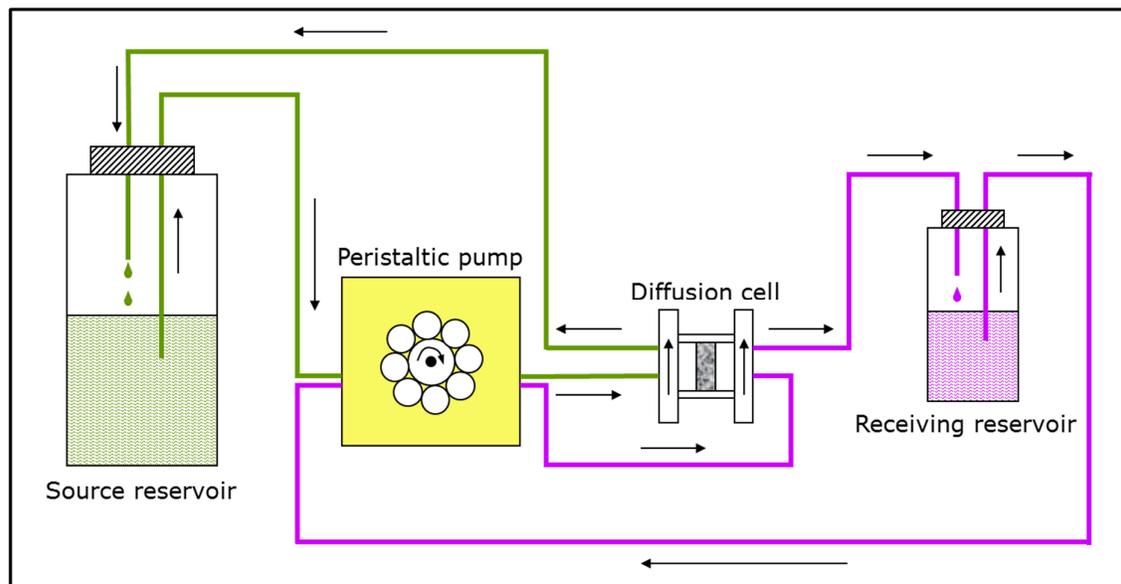

465 Immutable pore systems have been analysed for the calculation of macroscopic diffusivity.  
 466 Comparing the calculated results with experimental diffusion coefficients reported in the  
 467 literature, the realism of the model construction in terms of initial pore space geometry and

468 topology will be verified. In this work, the effects of pore shapes, sorption coefficient, and  
 469 velocities are analysed based on previous work.

470

### 471 3.5. Diffusion experiments

472 OPA bore core samples from the Mont Terri rock laboratory in Switzerland were used in all  
 473 diffusion experiments applying the experimental set-up described in Van Loon *et al.* [50] and  
 474 shown in Fig. 4. The samples (thickness: 11 mm, diameter: 25.5 mm) were placed in stainless  
 475 steel diffusion cells between two stainless steel filter plates (316L, pore diameter: 0.01 mm;  
 476 MOTT industrial division, Farmington, USA). Synthetic OPA pore water [51] was used as  
 477 background electrolyte in all diffusion experiments. Each diffusion cell was coupled with a  
 478 peristaltic pump (mod. Ecoline, Ismatec, IDEX Health & Science, Glattbrugg, Switzerland)  
 479 and a source and receiving reservoir filled with 200 mL and 20 mL synthetic OPA pore water,  
 480 respectively. The solutions were circulating through the end plates of the cells in order to  
 481 saturate the samples. The saturation time amounted to three weeks. Subsequently, the  
 482 solutions were replaced by fresh ones, whereby the source reservoir contained the tracer and  
 483 thus, tracer diffusion perpendicular to the clay bedding was started.

484

485 Fig. 4: Schematic depiction of the experimental set-up used in the diffusion experiments  
 486 (based on Van Loon *et al.* [50]).

487

488 At first, HTO through- and out-diffusion experiments were performed according to the  
 489 procedure described by Van Loon *et al.* [50] in order to determine values for the total  
 490 porosity ( $\theta$ ) of the clay samples ( $c_0(\text{HTO}) = 1000 \text{ Bq/mL}$ ). After that, the U(VI) in-diffusion

491 was studied ( $c_0(^{233}\text{U(VI)}) = 1 \times 10^{-6}$  mol/L). After 3 months, the diffusion experiments were  
492 stopped and the clay samples were removed from the cells. With the help of the abrasive  
493 peeling technique [52], U(VI) diffusion profiles were determined. The peeled layers were  
494 extracted for U(VI) content by 1 mol/L  $\text{HNO}_3$  (*p.a.*, Roth, Karlsruhe, Germany). The tracer  
495 concentrations in the extracts were determined by liquid scintillation counting (mod. TriCarb  
496 3100 TR, Perkin Elmer, Freiburg, Germany). All experimental results were evaluated using  
497 the commercial software COMSOL Multiphysics: Finite-element software package 3.5a  
498 (2008) and 4.2a (2011). A detailed description of all diffusion experiments can be found in  
499 Joseph *et al.* [25, 27].

500

501

502

503

504 **4 Results and discussion**

505

506 **4.1. Boundary value problems on graphs**

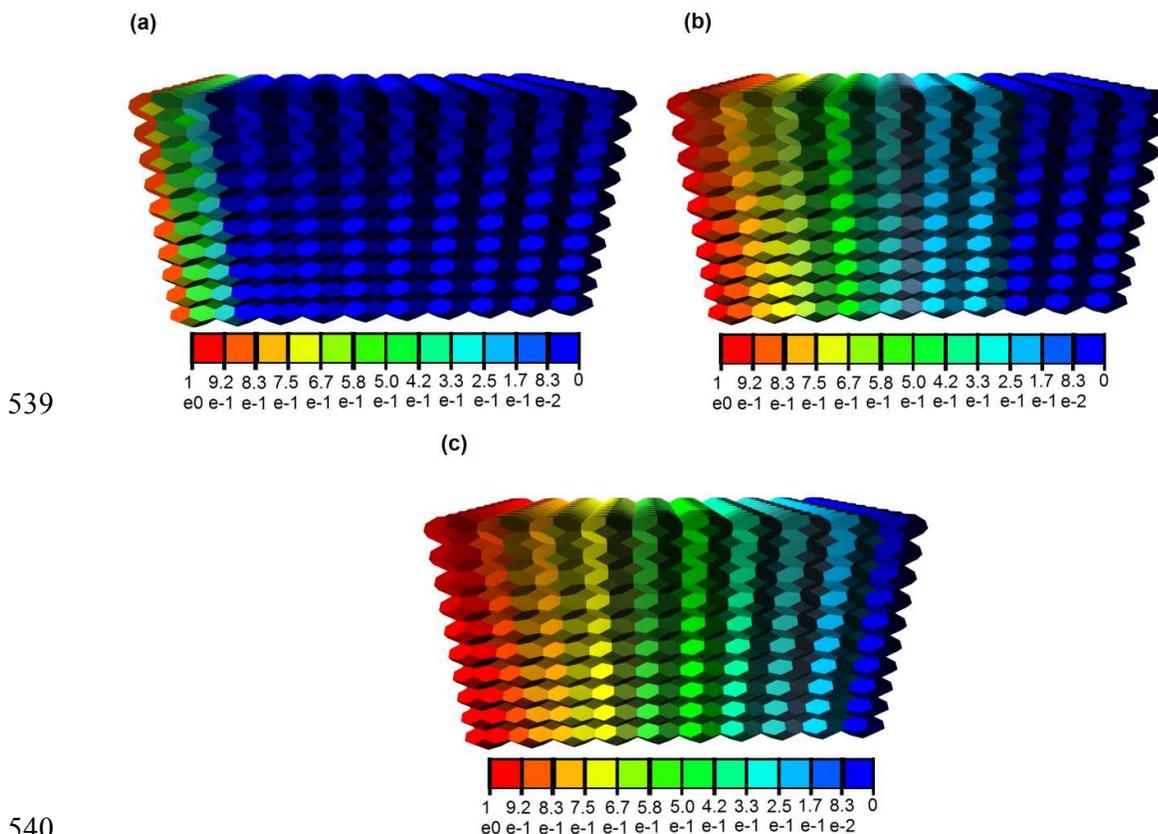

507 With respect to a coordinate system  $(X_1, X_2, X_3)$  normal to the square faces of the unit cell  
 508 (see Fig. 1), a pore network skeleton within the boxed region ( $0 \leq X_1 \leq N \cdot S_1$ ,  $0 \leq X_2 \leq N \cdot S_2$ ,  $0$   
 509  $\leq X_3 \leq N \cdot S_3$ ) was used. Here,  $S_1, S_2, S_3$ , are the cell sizes in the three coordinate directions and  
 510  $N$  is the number of cells in each coordinate direction. Pore networks were built on skeletons  
 511 with increasing  $N$  using the process from sub-sections 2.1-2.4. Statistically representative  
 512 distribution of pore sizes was obtained with relatively small number of cells, e.g., it was  
 513 sufficient that  $N > 5$  for the distributed pores to follow the experimental pore size distribution  
 514 closely. Further, the effect of the random spatial allocation of pores on results was analysed  
 515 using 10 different realisations for each  $N$ . It was found that for  $N = 20$ , the variation of results  
 516 from the average was reduced to under 10%. This was judged to be an acceptable accuracy  
 517 and the diffusivity results reported hereafter were obtained as the average values from 10  
 518 realisations on a skeleton with  $N = 20$ . This skeleton contains  $Nodes = 110860$  nodes, i.e.  
 519 potential pore junctions, and  $Edges = 533520$  bonds, i.e. potential pore locations.

520

521 Zero concentration of diffusing species is taken as initial conditions in all nodes. The  
 522 boundary conditions reflect a particular experimental setup, where concentrations  $c_0$  and  $c_1$ ,  
 523 are prescribed on two opposite boundaries, while the remaining four boundaries do not permit  
 524 flux. The selection of the two boundaries depends on the macroscopic transport properties  
 525 being analysed. Specifically, the boundary conditions used to calculate the macroscopic  
 526 transport properties parallel to bedding direction  $(1, 0, 0)$ ,  $D_1$ , are: prescribed concentration  $c_0$ ,  
 527 in all nodes on plane  $X_1 = 0$ ; prescribed concentration  $c_1$  in all nodes on plane  $X_1 = 20S_1$ ; zero  
 528 flux through all nodes on planes  $X_2 = 0$ ,  $X_2 = 20S_2$ ,  $X_3 = 0$ ,  $X_3 = 20S_3$ . For calculating the  
 529 macroscopic transport properties perpendicular to the bedding direction, say  $(0, 1, 0)$ ,  $D_2$ , the  
 530 boundary conditions are: prescribed concentration  $c_0$  in all nodes on plane  $X_2 = 0$ ; prescribed  
 531 concentration  $c_1$  in all nodes on plane  $X_2 = 20S_2$ ; zero flux through all nodes on planes  $X_1 = 0$ ,  
 532  $X_1 = 20S_1$ ,  $X_3 = 0$ ,  $X_3 = 20S_3$ .

533 One example of diffusion in the bedding direction for a system with unequal length  
 534 parameters and circular cross sectional pores is shown in Fig. 5 by the solute concentration  
 535 profiles at select times. The prescribed concentration  $c_0$  on plane  $X_1$  is  $1 \text{ mol/m}^3$  and the

536 prescribed concentration  $c_1$  on plane  $X_0$  is 0. These are snapshots taken from the whole  
 537 history obtained by numerical simulation based on Eq. (4). The profiles are shown on the  
 538 cellular assembly, rather than on the graph representing the pore network, for clarity.

540  
 541 Fig. 5: Concentration profiles of HTO [mol/m<sup>3</sup>] at time  $t = 0.1$  s (a),  $t = 0.5$  s (b), and  $t = 1$  s  
 542 (c). The pores are assumed with circular cross section.

543

#### 544 4.2. Effective diffusivity

545

546 The constructed pore networks exhibit macroscopic tortuosity (path lengthening), introduced  
 547 by the selection of transport pathways along the interfaces between solid phases regions. This  
 548 tortuosity depends on the material texture, represented here by the ratios of the cell length  
 549 parameters in three perpendicular directions. Experimental results show that tortuosity is  
 550 smaller in the bedding direction [26]. Therefore, we investigate the effect of larger cell length  
 551 in the bedding direction and smaller cell lengths in the directions perpendicular to bedding.  
 552 The results of different cell length ratios have been discussed in a previous paper [39]. It was  
 553 shown that the calculated effective diffusivity considering both carbonates and quartz as

554 particles is closest to the experimental value when the ratio of the cell length parameters is:  $S_1$   
 555 /  $S_2 = 2$  and the out-of-bedding directions are not differentiated, i.e.  $S_2 = S_3$  is assumed. In this  
 556 work, the same ratio of the cell length parameters and volume percentage of particles are  
 557 adopted. For cellular assembly of this given ratio, 10 realisations of pore spatial distributions  
 558 were analysed to obtain the transport in the bedding,  $S_1$ , and out-of-bedding,  $S_2$ , directions.  
 559 The results reported are the averaged values of these analyses.

560

561 The diffusion of tracer molecules in clay has shown that mainly neutral and cationic species  
 562 diffuse in the interlayer water, diffuse layer water and the free pore water [53]. Experiments  
 563 reported that the accessible porosity for HTO [25, 26, 37, 54] agrees very well with total  
 564 porosity in OPA [22], which implies that almost all the pores in OPA are available. The total  
 565 porosity has been used to simulate the effective diffusion coefficients of HTO in this work. In  
 566 Fig. 6, the effective diffusivities of HTO and U(VI) parallel and perpendicular to the bedding,  
 567  $D_1$  and  $D_2$ , are shown to increase as the average shape factor  $G$  increases. The calculated  
 568 effective diffusivity of HTO is in the following ranges:  $D_1 = 5.41 \times 10^{-11} \sim 17.10 \times 10^{-11} \text{ m}^2/\text{s}$ ;  
 569  $D_2 = 1.58 \times 10^{-11} \sim 5.03 \times 10^{-11} \text{ m}^2/\text{s}$  (see Fig. 6a). Reported experimentally obtained values for  
 570 HTO diffusion in OPA shown in Fig. 6a are in the range of  $D_1 = (5.4 \pm 0.4) \times 10^{-11} \text{ m}^2/\text{s}$  [26]  
 571 and  $D_2 = (1.48 \pm 0.03) \times 10^{-11} \text{ m}^2/\text{s}$  [25],  $(1.26 \pm 0.09) \times 10^{-11} \text{ m}^2/\text{s}$  [25],  $(1.23 \pm 0.06) \times 10^{-11} \text{ m}^2/\text{s}$   
 572 [26],  $(1.67 \pm 0.12) \times 10^{-11} \text{ m}^2/\text{s}$  [27],  $(1.33 \pm 0.11) \times 10^{-11} \text{ m}^2/\text{s}$  [27] determined for different bore  
 573 core samples. In OPA, the accessible porosity is different for the various species resulting in  
 574 different effective diffusivities. The increased diffusion of cations is explained either by  
 575 interlayer or by diffusion in the electrical double layer [37, 55] that surrounds the negatively  
 576 charged clay surface and contains an excess of cations [54, 56-61]. The diminished diffusion  
 577 of anions is due to their limited access to the interlayer space. This is caused by the overlay of  
 578 double layers. As a result the electric potential becomes considerably large [62].

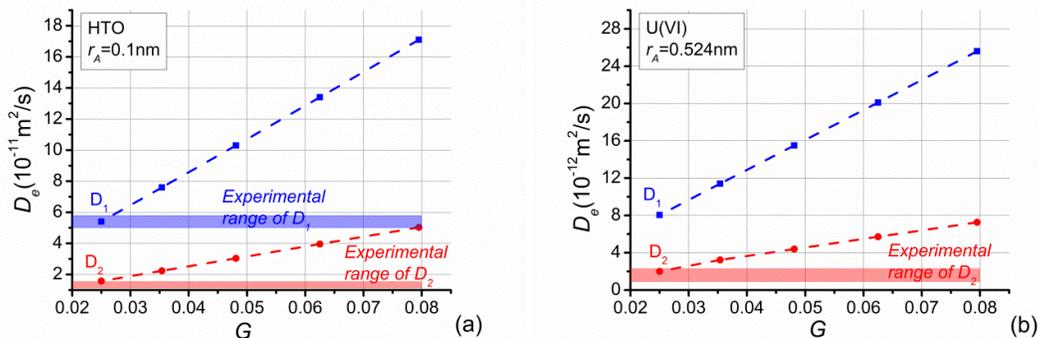

579

580 If in the model the diffusing U(VI) species is neutral, then the same initial accessible porosity  
 581 as for HTO can be assumed. The simulated effective diffusivity of U(VI) in the bedding  
 582 direction,  $D_1$ , (cf. Fig. 6b) is in the range of  $8.04 \times 10^{-12} \sim 2.56 \times 10^{-11} \text{ m}^2/\text{s}$ , and in the  
 583 perpendicular direction,  $D_2$ , is from  $1.98 \times 10^{-12}$  to  $7.26 \times 10^{-12} \text{ m}^2/\text{s}$ . Experimental data for  
 584 U(VI) in the perpendicular direction are  $1.5 \times 10^{-12} \sim 2.3 \times 10^{-12} \text{ m}^2/\text{s}$  [25, 27]. The simulated  
 585 results for HTO and U(VI) are in good agreement with experimental investigations when  
 586 average shape factor,  $G$ , is equal to 0.025 (cf. Fig. 6). In OPA, three types of water accessible  
 587 for diffusion can be distinguished. The solute, for instance a U(VI) species, enters freely the

588 larger pores, since it resides in an electrically neutral solution, the so-called free pore-water.  
589 On the net negatively charged clay surface, the water turns into a diffuse double layer. The  
590 charge deficiency can be balanced by exchangeable cations, anions are repulsed from the  
591 surface. The third type is interlayer water in the smectite fraction of OPA. It is considered to  
592 contain exchangeable cations only, which behave chemically and physically comparable to  
593 the surface complexed cations. The types of water or pore space accessible for diffusion  
594 depends on the diffusing species [22, 37, 63, 64]. Specifically, diffusion of cations is  
595 enhanced, and that of anions diminished, relative to a neutral tracer such as HTO [37]. The  
596 here discussed effective diffusivity excludes sorption effects of the U(VI) species,  
597  $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$ , on OPA during their migration, only the pure transport process is  
598 considered. Since the same approach was used for modelling HTO and U(VI) diffusion  
599 except that the radius of the diffusing species was changed, the observed difference of one  
600 order of magnitude in  $D_2$  for HTO and U(VI) can be attributed solely to size exclusion effects  
601 and not to charge effects of attracted or repulsed charged U(VI) species. It has been  
602 demonstrated in previous works [54, 65], that the amount of electrical double layer water is  
603 approximately equal to half of the porosity. This means that anions cannot access almost half  
604 of the porosity, manifested in anion exclusion effect on diffusivity. Hence, the effective  
605 diffusivity of  $\text{UO}_2(\text{CO}_3)_3^{4-}$  and U(VI) species should be different despite of their similar  
606 molecular sizes. Therefore, it can be concluded that the neutral  $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$  complex is  
607 not only the dominant U(VI) species in the OPA pore water solution in the source reservoir  
608 but also the main diffusing U(VI) species through OPA.

609

610 Overall, the model in this work can predict diffusion in OPA very well. The difference  
611 between the computational and the experimental results could be partially due to a difference  
612 between the microstructure characteristics of OPA obtained by Keller *et al.* [23, 24] used for  
613 model construction, and the clays used for experimental measurement of effective diffusion  
614 coefficients by Van Loon *et al.* [26] and Joseph *et al.* [25, 27].

615  
 616 Fig. 6: Calculated effective diffusivity of HTO (a) and U(VI) (b) in OPA as a function of  
 617 shape factor and accounting for carbonates and quartz as non-porous particles with combined  
 618 volume fraction of 0.35. Experimentally determined ranges of OPA effective diffusion  
 619 coefficients are shown for comparison.

620

### 621 4.3. Apparent diffusivity

622 To investigate the effects of the shape factor on sorption, apparent diffusivities of U(VI) with  
 623 different average shape factors are analysed and presented in Fig. 7(a). It is obvious that the  
 624 increase of the average shape factor in the system yields an increase of apparent diffusivities  
 625 of U(VI) in both directions investigated. Because the shape factor is the ratio between cross  
 626 section area and perimeter, smaller shape factors lead to smaller ratios between pore volume  
 627 and surface area. The larger the surface area the more species adsorb onto the pore wall. The  
 628 variation of U(VI) apparent diffusivities is bigger than the growth of U(VI) effective  
 629 diffusivities when the average shape factor increases from 0.025 to 0.08. In addition, the  
 630 change of apparent diffusivities in the bedding direction is larger than apparent diffusivities  
 631 perpendicular to the bedding plane. This is due to the fact that elongated pores are distributed  
 632 in the bedding direction. The shape factor only affects cross sectional shape.

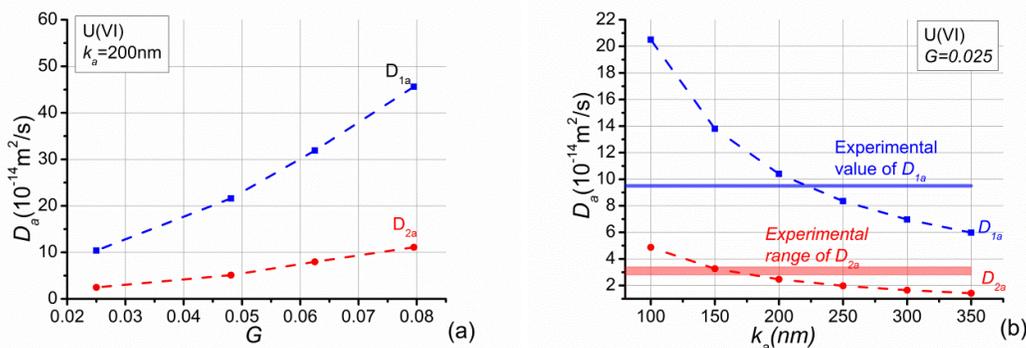

633

634 Because effective diffusivities of U(VI) agree well with experimental values when the  
 635 average shape factor,  $G$ , equals to 0.025, this value of  $G$  is adopted to study sorption effects  
 636 of U(VI) in OPA. We assumed that linear sorption occurs at pore-scale according to  
 637 experimental investigation [35]. Apparent diffusivities of U(VI) species are shown in Fig. 7(b)  
 638 as a function of distribution coefficients,  $k_a$ . It is clear that the increase of  $k_a$  yields reductions  
 639 of the apparent diffusivity,  $D_{1a}$  and  $D_{2a}$ . Because the adsorbed mass is dependent on the value  
 640 of  $k_a$ , more species will be adsorbed when  $k_a$  increases. As a consequence, migration of the  
 641 U(VI) species retards because of their stronger interaction with the OPA pore walls. In

642 addition, since more species are adsorbed onto the pore-wall, the cross section of pores  
 643 allowed for diffusion becomes smaller and thus the accessible pore space will be reduced.  
 644 Notably, the decrease of the apparent diffusivity becomes slowly as the adsorption coefficient  
 645 increases. This is an illustration of the non-linear effect of the sorption in the system.

646

647 The calculated results of apparent diffusivities are in the following ranges:  $D_{1a} = 8.35 \times 10^{-14} \sim$   
 648  $2.05 \times 10^{-13} \text{ m}^2/\text{s}$ ;  $D_{2a} = 1.98 \times 10^{-14} \sim 4.87 \times 10^{-14} \text{ m}^2/\text{s}$ , see Fig. 7(b), when  $k_a$  decreases from  
 649 250 nm to 100 nm. Reported experimentally obtained values for U(VI) complexes diffusion  
 650 in OPA are  $D_{1a} = 9.5 \times 10^{-14} \text{ m}^2/\text{s}$  [28],  $D_{2a} = 2.8 \times 10^{-14} \sim 3.4 \times 10^{-14} \text{ m}^2/\text{s}$  [25, 27],  $2.8 \times 10^{-14}$   
 651  $\text{m}^2/\text{s}$  [28]. These ranges are given in Fig. 7(b). Direct comparison shows that the simulation  
 652 and the experimental results are in reasonable agreement when  $k_a$  is about 200 nm. The  
 653 experimental distribution coefficients  $k_d$  measured by experiments were parallel to the  
 654 bedding:  $0.0142 \text{ m}^3/\text{kg}$  [28], perpendicular to the bedding:  $0.025 \pm 0.003 \text{ m}^3/\text{kg}$  [25],  
 655  $0.038 \pm 0.005 \text{ m}^3/\text{kg}$  [27],  $0.0138 \text{ m}^3/\text{kg}$  [28]. Since  $k_a$  is the distribution coefficient,  $k_d$ ,  
 656 normalised by surface area, and the surface area obtained by ethylene glycol monoethyl ether  
 657 for OPA varies from 80 to 107  $\text{m}^2/\text{g}$  (the average value is 94  $\text{m}^2/\text{g}$ ) [22], the experimental  $k_a$   
 658 values range from 128 nm to 350 nm. This is very close to the simulated value of  $k_a$ . The  
 659 sorption of U(VI) species is therefore linear.

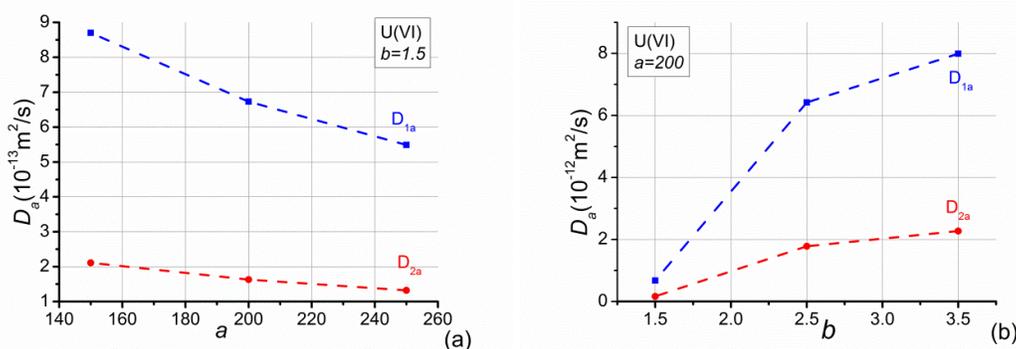

660

661 Fig. 7. Simulated apparent diffusivity of U(VI) in OPA. (a) the dependence on shape factor  
 662 when distribution coefficient,  $k_a$ , equals 200 nm; (b) as a function of  $k_a$ , when  $G = 0.025$ ,  
 663 experimentally determined ranges of  $D_a$  values are shown for comparison.

664

665 The pore-scale Freundlich isotherm sorption,  $s = ac^b$  (cf. Eq. (16)), is also studied in this  
 666 work. Since this sorption equation is dependent on the pore-local concentration variation of  
 667 solutes, the concentration applied at the boundaries must be clarified. This is different for the  
 668 analysis of effective diffusion and linear sorption where the results are independent of the

669 prescribed concentration difference on the boundaries. We apply  $C_0 = 0.05 \text{ mol/m}^3$  at  $X_0 = 0$ ,  
 670  $C_l = 0$  at  $X_l = 20S_l$ , and no flux at other boundaries. The effects of parameters  $a$  and  $b$  on the  
 671 apparent diffusivities are shown in Fig. 8. In Fig. 8(a), the increase of  $a$  yields a reduction of  
 672 the apparent diffusivities of U(VI) in both directions when  $b = 1.5$ . The changes are similar  
 673 with the situation of linear sorption,  $s = k_a c$ . In Fig. 8(b), the apparent diffusivities of U(VI)  
 674 in both directions increase as  $b$  increase. The increase of apparent diffusivities becomes  
 675 slowly with increasing  $b$ . This is due to the fact that the adsorbed mass becomes less as the  
 676 parameter of  $b$  increases. The maximum values of apparent diffusivities will be very close to  
 677 their effective diffusivities when  $b$  increases.  
 678

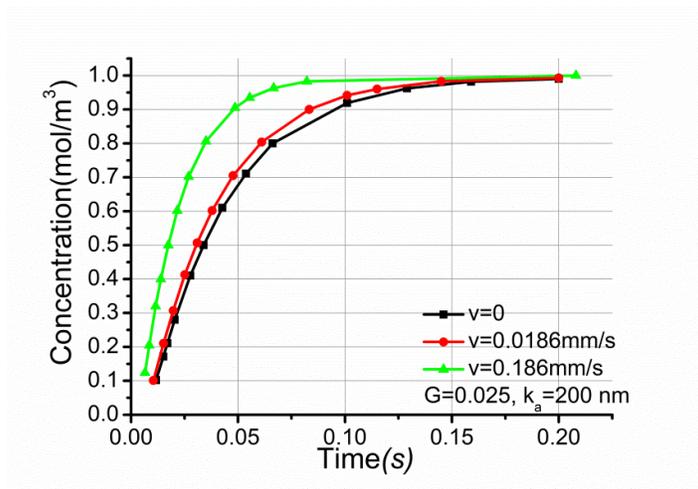

679  
 680 Fig. 8: Simulated apparent diffusivity of U(VI) in OPA by assuming a nonlinear sorption.  
 681 Data are presented as a function of the Freundlich coefficient  $a$  (a) and the Freundlich  
 682 exponent  $b$  (b). The shape factor equals to 0.025.  
 683

#### 684 4.4. Velocity effect on transport property

685

686 Although hydraulic conductivity is very slow in OPA, it may be crucial for mass transport in  
 687 other porous media. To illustrate the mechanism of diffusion-sorption-convection in porous  
 688 media, we still use OPA as an example. The effect of velocity on transport of uranium species  
 689 is considered. The shape factor is 0.025 and the distribution coefficient  $k_a$  is 200 nm. The  
 690 evolution of uranium concentration at the outlet surface with time for different velocities is  
 691 described in Fig. 9. Obviously, convection accelerates transport of species through the pore  
 692 network model. The larger the velocity through the pore network model, the faster the species  
 693 arrive the outlet surface. There is not much variation in the time evolution of the outlet  
 694 concentration when velocity increases from 0 to 0.186 mm/s. This is in agreement with the  
 695 fact that not convection but molecular diffusion is the main transport mechanism for  
 696 radionuclides in OPA.

697

698 Fig. 9: Time history of uranium concentration at the outlet surface for different velocities, the  
 699 distribution coefficient  $k_a$  is 200 nm, the pore shape factor is 0.025.

700

## 701 5 Conclusions

702

703 A discrete model for mass transport through porous media has been proposed to balance  
 704 incomplete knowledge of geometrical and topological pore system characteristics.

705

706 The effect of clay's texture on the transport properties has been investigated by analysing the  
 707 transport of HTO and U(VI) through OPA. The anisotropy and heterogeneity of the clay can  
 708 be simulated via different length parameters and percentage of pores in different directions.  
 709 Different pore shapes are also taken into account in this model, which is very important for  
 710 multi-phase transport. Calculated diffusion coefficients are within the ranges of experimental  
 711 data. The results suggest that U(VI) diffuses as neutral species,  $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$ , through  
 712 OPA. Because only species in the source reservoir solution are known in experiments, the  
 713 methodology proposed in this work could clarify the kind of U(VI) species (anion, cation or  
 714 neutral species) diffusing in OPA. In addition, the idea has been extended to account for  
 715 sorption and convection. Physical sorption is simulated in each pore, which is more accurate  
 716 and realistic compared to previous coarse grained mathematical formula by changing pore  
 717 radii [1].

718

719 Although this work has used a particular material to illustrate the methodology and its  
 720 application, the model is suitable for modelling and simulation of other micro- and meso-  
 721 porous materials. The methodology proposed in this work can be used to study sorption of

722 species that may not be easily studied by classical in-diffusion or through-diffusion methods,  
723 for example, when the species is adsorbed onto laboratory materials (e.g., cells, vessels, and  
724 tubing).

725

726 The proposed model can be potentially used for coupling with deformation and fracture of  
727 porous media, where the pore system and the solid phase, represented as dual graphs, will  
728 interact effectively. Models mimicking the coupling are possible and are subject of ongoing  
729 work. For example, our immediate plans are to study the effect of micro-cracking due to  
730 thermo-mechanical loads on the diffusion with application to long-term behaviour of OPA in  
731 a nuclear wastes repository. The goal with the concept development is to have a set of  
732 discrete models, i.e. PNM accounting for transport mechanism and lattice models of the solid  
733 phase developed for analysis of damage evolution via micro-cracking [19], that evolve  
734 concurrently at their own rates and inform each other about changes in their structures. Such  
735 a coupled problem could be of great interest in many disciplines, e.g., shale gas extraction,  
736 dams, and underground cavities in hydropower engineering. In these applications, the  
737 evolution of permeability rather than diffusivity of the medium is required, but the  
738 methodology developed in this work would be the same.
